With the patient supine, and the occiput cupped, the segment is extended by lifting the superior vertebra forward (obviating the need to extend the entire spinal region) and allowing the patient's head and neck to bend over the fulcrum, created by the clinician's fingers. While maintaining the extended position (by pushing the transverse processes of the segment anteriorly), the segment is side bent left and then right around its axis of motion and translated contralaterally (Fig. 25-44). During the translation, very slight head motion should occur. Rather, a slight tilting around each segmental axis occurs, using gentle pressure via the fingertips or the fleshy part of the second metacarpophalangeal joint. The slight side bending before the translation is to fix the axis at that segmental level. During left side bending, the left side of the segment is maximally extended, while the right side is moved toward its neutral position. The opposite occurs with right side bending.

The range of motion of the side bending and the end-feel of the translation is evaluated for normal, excessive, or reduced motion states. If the end-feel of the translation is normal, but the side bending is restricted, the hypomobility is extra-articular (myofascial) (see Table 25-8).

To test the intersegmental mobility of the lower cervical/upper thoracic region, the patient is positioned in side lying with their arm over the end of the table to stabilize the thorax and their head cradled by the clinician (Fig. 25-45). The patient's neck is placed in the neutral position of the head on the neck and the neck on the trunk. Once in this position, the clinician uses the index finger to monitor intersegment motion between the spinous processes, while passively moving the patient's head and neck into flexion, extension, side bending, and then rotation.

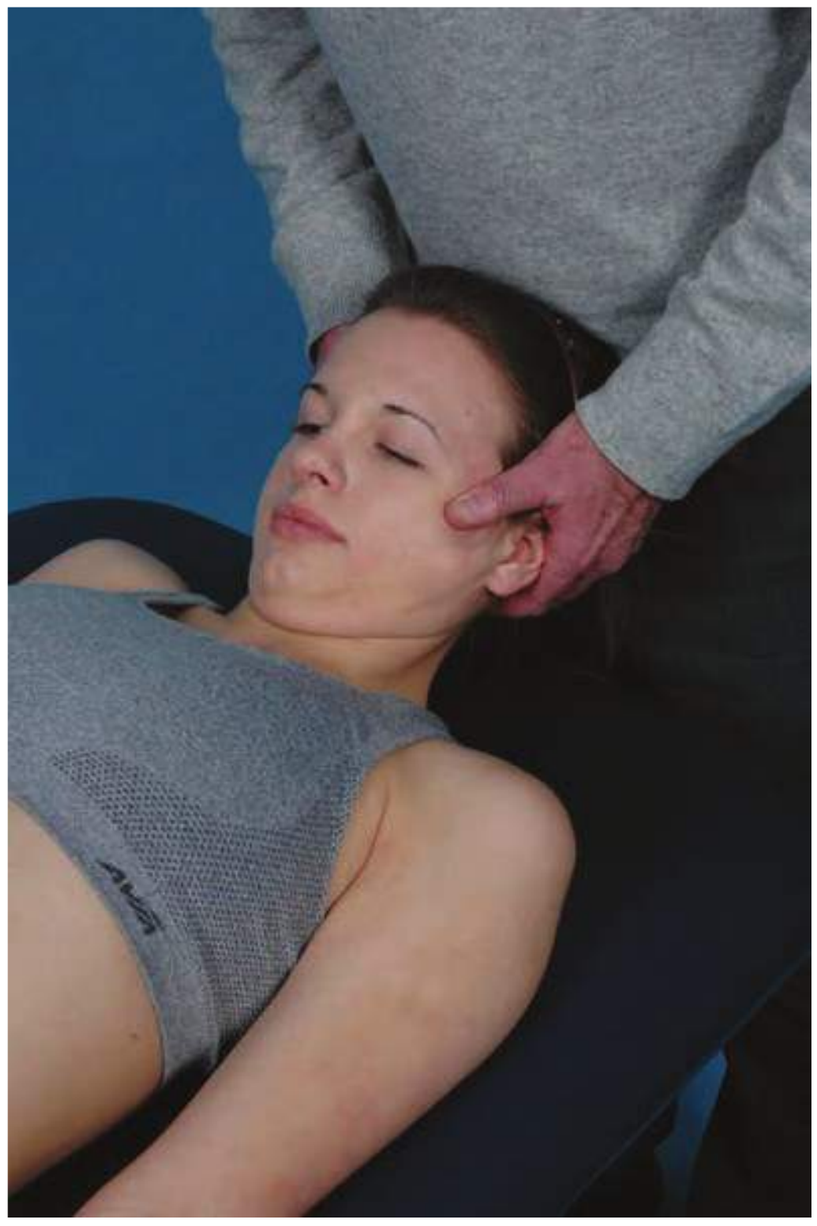

FIGURE 25-43 Translational glides of cervical spine in flexion.

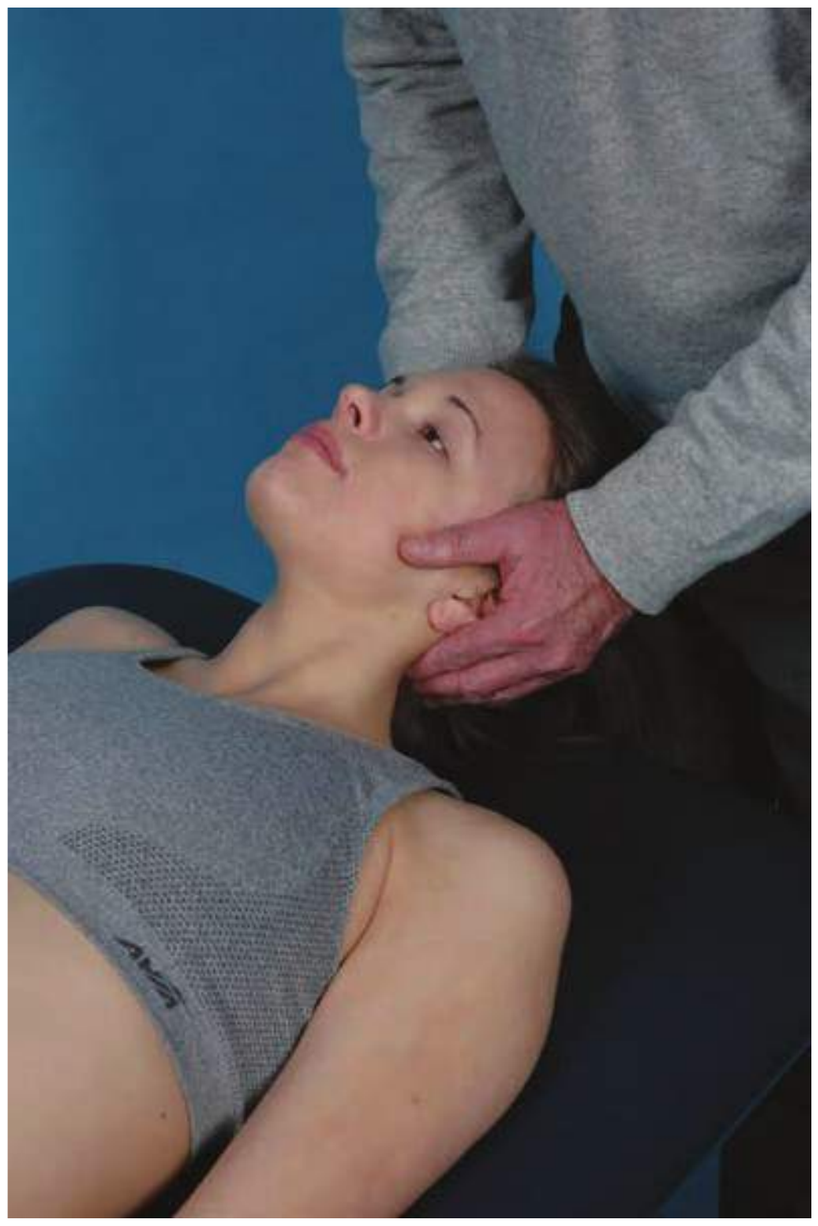

FIGURE 25-44 Translational glides of cervical spine in extension.

Because of the unreliability of mobility testing in extension, the information gleaned from motion testing is more likely to be more reliable in determining the side of the closing restriction.

FIGURE 25-45 Segmental mobility testing of the cervicothoracic junction.

Clinically, it would appear that the zygapophyseal joints are more involved with the rotational aspect of the coupling, functioning to prevent excessive rotation, whereas the uncovertebral joints appear to be more involved with pure side-bending motions. Although this concept may not hold up to scientific scrutiny, it tends to work well in the clinic. T us, a glide restriction found in flexion, extension, and neutral would tend to implicate a problem with the uncovertebral joint.

While it is not necessary, or sometimes not possible, to make a diagnosis from these tests, some useful deductions can be made, and these will direct the ensuing joint glide tests to the appropriate joint. Remember that if the end-feel of the glide suggests that motion is still occurring at the end of the available range, the joint is not the cause of restriction (think muscle).

Passive Physiologic Accessory Intervertebral Mobility Tests

T e passive physiologic accessory intervertebral mobility (PPAIVM) tests investigate the degree of linear or accessory glide that a joint possesses and are used on segmental levels where there is a possible hypomobility, to help determine if the motion restriction is articular, periarticular, or myofascial in origin. In other words, they assess the amount of arthrokinematic motion, as well as the quality of the end-feel. T e motion is assessed in relation to the patient's body type, and age and the normal range for that segment and the end-feel is assessed. A variety of techniques can be used to assess the joint glides in this region. Unless otherwise stated, the patient is positioned in supine with their head resting on the treatment table. T e cervical spine is positioned in midrange in relation to flexion, extension, side bending, and rotation. T e clinician is positioned at the patient's head. For each of the tests, the clinician assesses the quantity and quality of motion and makes comparisons to the contralateral side, or to the adjacent segment, as appropriate.

Distraction. Using both hands, the clinician wraps around the occiput of the patient using the web space of the hands. T e clinician leans backward and gently applies a force to the chin and occiput to distract the vertebral bodies from one another (Fig. 25-46). Most of the force should be directed to the occiput.

Segmental Translation. In the following example, a let side bending of C3–4 will be described. T e patient is positioned in supine, with the clinician at the head of the bed. T e clinician cradles the patient's head with both hands and places the pad of the index fingers of each hand across the neural arches of C3. T e clinician then applies a right translatory (shearing) force on the C3 neural arch, while keeping the head and upper neck in neutral. A firm end-feel should be achieved as the sot tissue slack is taken up in the joints below, at the C3–4 level, as there is a normal congruent set of motions occurring, for example, let side bending/rotation with right translation (Fig. 25-47). However, at the levels below there is an incongruent set of motions occurring, for example, right side bending/rotation with right translation. T e diagnostic accuracy for these tests are unknown, but the reliability scores from one study[174] were kappa = 0.03–0.63 (mobility) and ICC = 0.22–0.80 (pain).

FIGURE 25-46 General distraction of cervical spine in supine.

Rotation. To test the motions involved with cervical rotation, the patient is positioned in supine, and the cervical spine is placed in the range in relation to flexion, extension, side bending, and rotation. T e clinician stands at the patient's head. Leaning forward, the clinician rests the abdomen against the top of the patient's head. Using one hand, the clinician grips the inferior segment posteriorly using the web space of the hand, and laterally with the index finger and thumb. Using a similar grip, the clinician uses the other hand to wrap around the superior segment. While stabilizing the inferior segment, the clinician glides the superior segment into rotation (Fig. 25-48).

FIGURE 25-47 Left side bending/rotation with right translation at the C3–4 level.

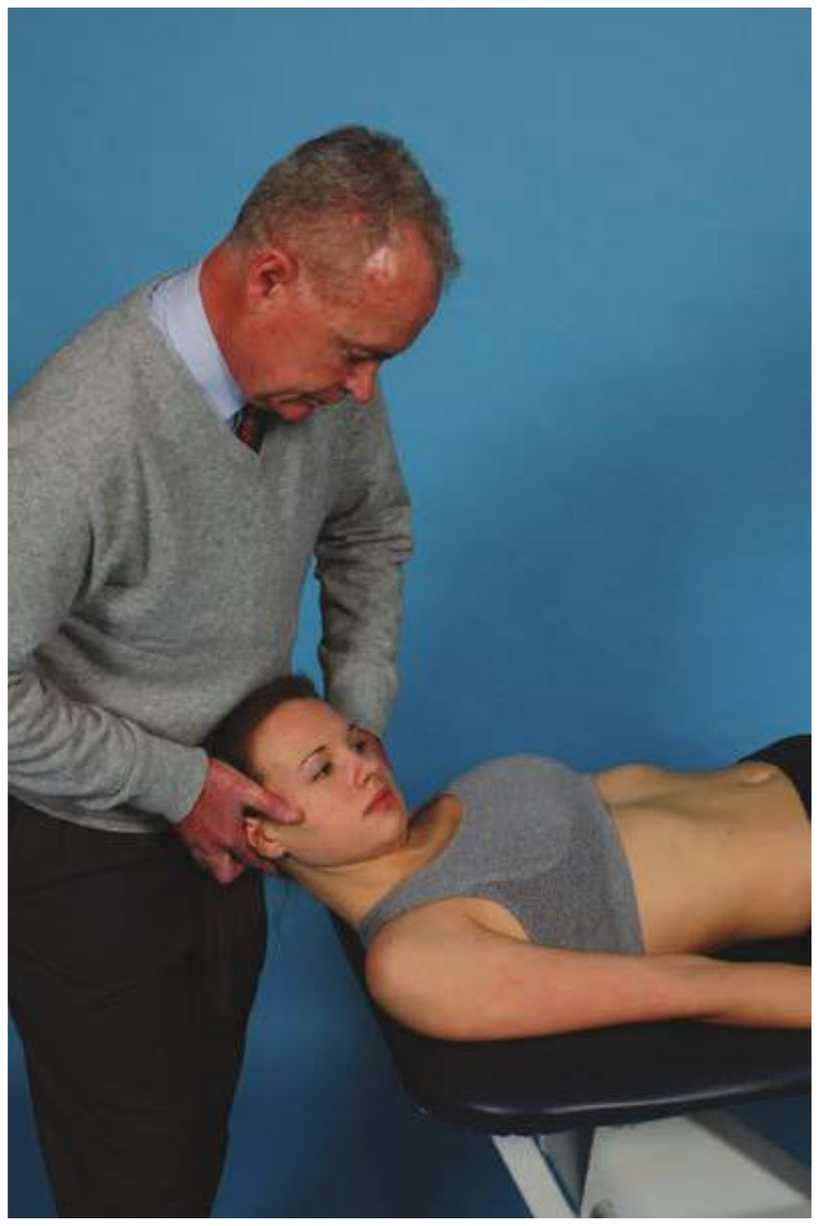

FIGURE 25-48 Rotation of superior segment in supine.

Combined Motions. Leaning forward, the clinician rests the abdomen against the top of the patient's head. Using one hand, the clinician grips the inferior segment posteriorly using the web space, and laterally with the index finger and thumb. Using a similar grip, the clinician uses the other hand to wrap around the superior segment. T e patient's head is then guided into the four quadrants: flexion and rotation to the right (Fig. 25-49), flexion and rotation to the let , extension and rotation to the right, and extension and rotation to the let .

Cervical Stress Tests

Depending on the irritability of the segment, a variety of tests can be used to assess for instability. It is worthwhile to start gently with segmental palpation and gentle posteroanterior pressures before progressing to the other techniques. Unless indicated, the patient is positioned supine. T e following tests are performed to examine segmental stability.

Posteroanterior Spring Test

T e patient is positioned in prone for anterior stability testing; the clinician places his or her thumbs over the posterior aspects of the transverse processes of the inferior vertebra of the segment being tested. To ensure patient comfort during

FIGURE 25-49 Flexion and rotation to the right in supine.

this test, the thumbs must be placed under (posterior to) the SCM, rather than over it, and must function merely to stabilize the maneuver, exerting no pushing force. T e vertebra is then pushed anteriorly (Fig. 25-50), and the clinician feels for the quality and quantity of movement. A rotational component can be added to the test by applying force on only one of the transverse processes.

CLINICAL PEARL

In the cervical spine, A-P pressure should ideally be performed over the costal process, as opposed to the transverse process, to avoid performing carotid sinus pressure on the carotid artery, thereby reducing the possibility of either a drop in heart rate or blood pressure.[177]

FIGURE 25-50 P-A pressures of cervical spine.

FIGURE 25-51 Transverse shear test.

For posterior stability testing, the thumbs are placed on the anterior aspect of the superior vertebra, and the index fingers are on the posterior aspect (neural arch) of the inferior.[166] T e inferior vertebra is then pushed anteriorly on the superior one, producing a relative posterior shear of the superior segment.

It is likely that this test is highly sensitive at implicating the dysfunctional level but is not specific for the causative pathological process. However, the diagnostic value of this test is as yet unknown.

Transverse Shear

T e transverse shear test should not be confused with the lateral glide tests previously mentioned. T e lateral glide tests are used to assess joint motion, whereas the transverse shear test assesses the stability of the segment. Although motion is expected to occur in the lateral glide test, no motion should be felt to occur with the transverse shear test.[178]

T e inferior segment is stabilized, and the clinician attempts to translate the superior segment transversely using the sot part of the metacarpophalangeal joint of the index finger[166] (Fig. 25-51). T e end-feel should be a combination of capsular and slightly springy. T e test is then reversed so that the superior segment is stabilized, and the inferior segment is translated under it.

T e test is repeated at each segmental level and for each side. T e diagnostic value of this test is as yet unknown.

Craniovertebral Ligament Stress Tests

T e tests for these ligaments, which include the alar and transverse ligament, are described in Chapter 23.

Distraction and Compression

The patient is supine, and the clinician sits or stands at the patient's head. The clinician cups the patient's occiput in one hand and rests the anterior aspect of the ipsilateral shoulder on the patient's forehead. The other hand stabilizes at a level close to the base of the neck[166]. A traction–compression–traction force is applied. This test can also be performed with the patient in sitting (Figs. 25-52 and 25-53). The clinician notes the quality and quantity of motion.

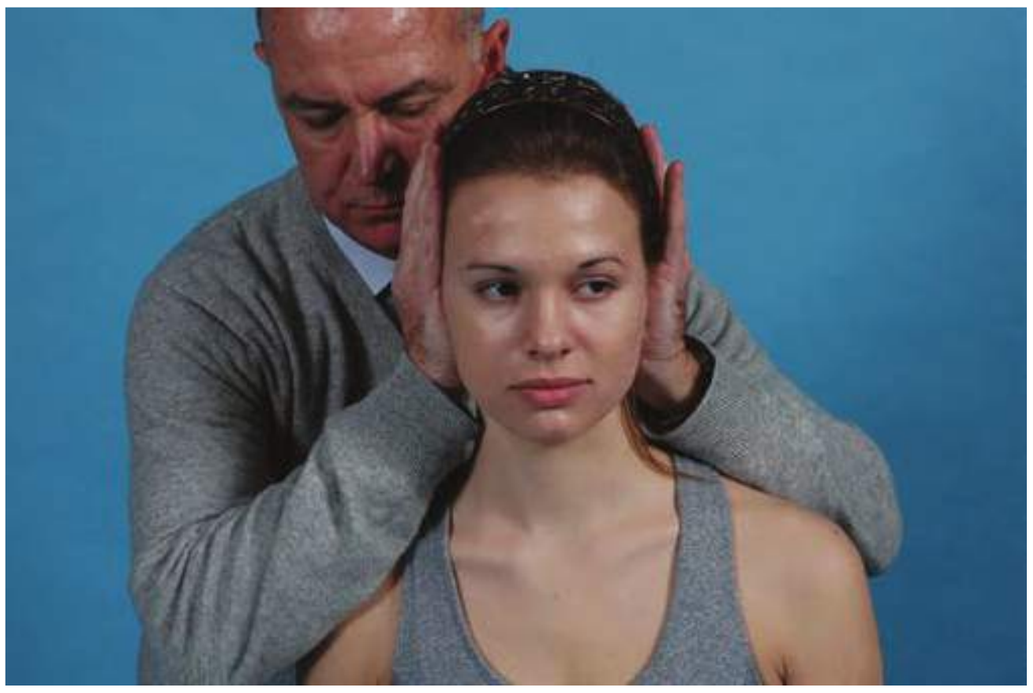

FIGURE 25-52 Cervical distraction in sitting.

Pain reproduced with compression suggests the presence of the following:

- Disk herniation;
- Vertebral end plate fracture;
- Vertebral body fracture;
- Acute arthritis or joint inflammation of a zygapophyseal joint; and
- Nerve root irritation, if the radicular pain is produced.

Reproduction of pain with cervical distraction suggests the presence of the following:

- Spinal ligament tear;
- Tear or inflammation of the AF;
- Muscle spasm;
- Large disk herniation; and
- Dural irritability (if a nonradicular arm or leg pain is produced).

Functional Assessment

A number of formal ways of measuring neck function are available and include the following:

- The neck disability index (NDI) is a patient survey instrument (see Table 5-3) that contains 10 items (7 related to activities of daily living, 2 related to pain, and 1 item related to concentration). The NDI is a revision of the Oswestry index and is designed to measure the level of reduction in activities of daily living in patients with neck pain. The NDI has been widely researched and validated,[179] and its test–retest reliability has been found to be 0.89.[179]
- The Northwick Park Neck Pain Questionnaire (Table 25-13)[180] contains nine sections that cover activities likely to affect neck pain. Each section contains five statements related to the patient's perceived level of difficulty performing the activity of the section. Scores on the questionnaire range from 0% to 100%, with 0% being associated with no disability and 100% with severe disability. The questionnaire has good short-term repeatability and internal consistency.[181]

FIGURE 25-53 Cervical compression in sitting.

Special Tests

In most cases, the special tests are only performed if there is some indication that they would be helpful in arriving at a diagnosis. However, in the cervical spine, in addition to the cervical stress tests, the vertebral artery should also be assessed (see Chapter 24), especially if the plan is to place the cervical spine in the extremes of extension, or extension and rotation as part of the examination or treatment.

Temporomandibular Joint Screen

Because the TMJ (see Chapter 26) can refer pain to this region, the clinician is well advised to rule out this joint as the cause for the patient's symptoms.

The patient is asked to open and close the mouth and to laterally deviate the jaw, as the clinician observes the quality and quantity of motion and notes any reproduction of symptoms.

Neurodynamic Mobility Tests

Upper limb tension testing (see Chapter 11) may serve a useful role in differentiating between the involvement of neural and nonneural structures.[10]

Lhermitte's Symptom or "Phenomenon"

This is not so much a test as it is a symptom, described as an electric shock-like sensation that radiates down the spinal column into the upper or lower limbs when flexing the neck (see Chapter 3).

Flexion Rotation Test

This test is used to determine the presence of a cervicogenic headache and is both a range of motion and provocation test. The patient is positioned in supine, and resting symptoms are noted. The patient is asked to maximally flex his or her neck and to hold that position. Using both hands, the clinician applies a full rotational force to both sides and notes any changes in symptoms (Fig. 25-54). The test is considered positive for a cervicogenic headache if a loss of 10 degrees or greater is noted when comparing both sides. Given the testing position, it is likely that C1–2 is the tested level. A single blind, age and gender matched, comparative measurement study by Hall and Robinson[182] found this test to have a sensitivity of 86% and a specificity of 100% (QUADAS score of 12).

TABLE 25-13 The Northwick Park Neck Pain Questionnaire

Parameter	Status	Points
Neck pain intensity	I have no pain at the moment.	0
	The pain is mild at the moment.	1
	The pain is moderate at the moment.	2
	The pain is severe at the moment.	3
	The pain is the worst imaginable at the moment.	4
Neck pain and sleeping	My sleep is never disturbed by pain.	0
	My sleep is occasionally disturbed by pain.	1
	My sleep is regularly disturbed by pain.	2
	Because of pain I have less than 5 hours sleep in total.	3
	Because of pain I have less than 2 hours of sleep in total.	4
Pins and needles or numbness in the arms at night	I have no pins and needles or numbness at night.	0
	I have occasional pins and needles or numbness at night.	1
	My sleep is regularly disturbed by pins and needles or numbness.	2
	Because of pins and needles I have less than 5 hours sleep in total.	3
	Because of pins and needles or numbness I have less than 2 hours of sleep in total.	4
Duration of symptoms	My neck and arms feel normal all day.	0
	I have symptoms in my neck or arms on waking which last less than 1 hour.	1
	Symptoms are present on and off for a total period of 1–4 hours.	2
	Symptoms are present on and off for a total of more than 4 hours.	3
	Symptoms are present continuously all day.	4
Carrying	I can carry heavy objects without extra pain.	0
	I can carry heavy objects but they give me extra pain.	1
	Pain prevents me from carrying heavy objects but I can manage medium weight objects.	2
	I can lift only light-weight objects.	3
	I cannot lift anything at all.	4
Reading and watching TV	I can do this as long as I wish with no problems.	0
	I can do this as long as I wish if I'm in a suitable position.	1
	I can do this as long as I wish but it causes extra pain.	2
	Pain causes me to stop doing this sooner than I would like.	3
	Pain prevents me from doing this at all.	4
Working/housework	I can do my usual work without extra pain.	0
	I can do my usual work but it gives me extra pain.	1
	Pain prevents me from doing my usual work for more than half the usual time.	2
	Pain prevents me from doing my usual work for more than a quarter of the usual time.	3
	Pain prevents me from working at all.	4
Social activities	My social life is normal and causes me no extra pain.	0
	My social life is normal but increases the degree of pain.	1
	Pain has restricted my social life but I am still able to go out.	2
	Pain has restricted my social life to the home.	3
	I have no social life because of pain.	4
Driving[a]	I can drive whenever necessary without discomfort.	0
	I can drive whenever necessary but with discomfort.	1
	Neck pain or stiffness limits my driving occasionally.	2
	Neck pain or stiffness limits my driving frequently.	3
	I cannot drive at all due to neck symptoms.	4
	TOTAL SCORE:	

Instructions: The questionnaire has been designed to give us information as to how your NECK PAIN has affected your ability to manage in everyday life. Please answer every question and mark in each section ONLY THE ONE BOX which applies to you. We realize you may consider that two of the statements in any one section relates to you but PLEASE JUST MARK THE BOX WHICH MOST CLOSELY DESCRIBES YOUR PROBLEM.

[a]The question on driving is omitted if the patient did not drive a car when in good health.

FIGURE 25-54 Flexion rotation test.

Scalene Cramp and Relief Tests

For the scalene cramp test, the patient is positioned in sitting and is asked to turn the head toward the painful side and pull the chin down into the supraclavicular fossa (Fig. 25-55). This position causes contraction of the scalenes and should reproduce distal radiation of pain if the scalenes are involved. The scalene relief test is performed by asking the patient to place the forearm against the forehead on the involved side. This position increases the space between the clavicle and the scalenes and is positive for scalene dysfunction if it relieves the patient's pain. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Spurling Test

Provocative tests for cervical radiculopathy include the foraminal compression test or Spurling test.[183] The patient

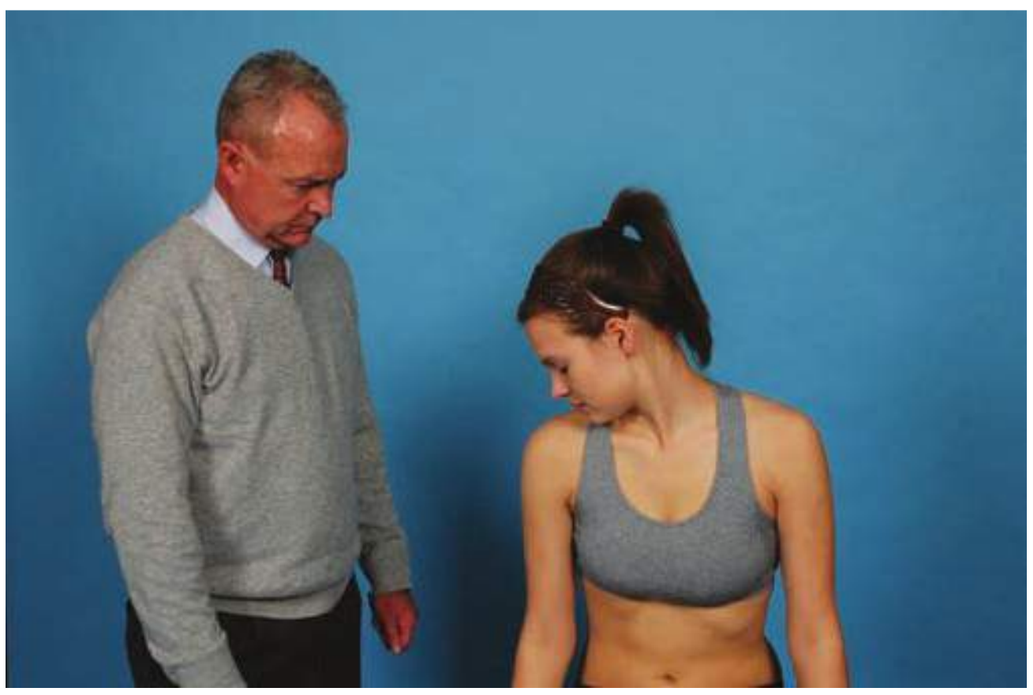

FIGURE 25-55 Scalene cramp test - sidebending and extension.

FIGURE 25-56 Spurling test.

is positioned in sitting. The test is performed by asking the patient to rotate the head to the uninvolved side and then to the involved side. The clinician then carefully applies a downward pressure on the head, with the head in neutral. The test is considered positive if pain radiates into the limb ipsilateral to the side at which the head is rotated.[184] Neck pain with no radiation into the shoulder or arm does not constitute a positive test. Conditions such as stenosis, cervical spondylosis, osteophytes, or disk herniation are implicated with a positive test. There are few methodologically sound studies that assess the interexaminer reliability, sensitivity, and specificity of this test. The literature appears to indicate high specificity and low sensitivity.[185] Therefore, the test is not useful as a screening test, but it is clinically useful in helping to confirm a cervical radiculopathy.

Modifications to this test have been advocated, which divide the test into three stages, each of which is more provocative.[119] If symptoms are reproduced, the clinician does not progress to the next stage. The first stage involves applying compression to the head in neutral. The second stage involves compression with the head in extension. The final stage involves compression with the head in extension and sidebending to the uninvolved side (Fig. 25-56), and then to the involved side. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of these variations.

Valsalva

The patient is positioned in sitting and is instructed to hold his or her breath and then "bear down" as in performing a bowel movement. Reproduction of the consistent pain while bearing down is considered a positive response for a disk herniation (Table 25-14).

TABLE 25-14 Evidence-based Tests for Cervical Radiculopathy

Test	Reliability	Sensitivity	Specificity	LR+	LR–	DOR	QUADAS Score
Spurling[a]	NT	30	93	4.3	0.75	5.69	9
Valsalva[b]	0.69 kappa	22	94	3.67	0.82	4.41	10

Shoulder Abduction Test

The shoulder abduction test[186,187] is used to test for the presence of radicular symptoms. The patient is positioned sitting or supine and is asked to elevate the arm through abduction so that the hand or forearm rests on top of the head (Fig. 25-57). If this position relieves or decreases the patient's symptoms, a cervical extradural compression problem, such as a herniated disk, or nerve root compression should be suspected. The literature seems to indicate high specificity with low sensitivity for this test (Table 25-14). The specific segmental level can be determined by the dermatome distribution of the symptoms. If the symptoms are increased with this maneuver, the implication is that pressure is increasing in the interscalene triangle.[187]

Brachial Plexus Compression Test

The patient is positioned in sitting and is asked to side bend the head to the uninvolved side. The clinician applies firm pressure to the brachial plexus by squeezing the plexus lateral to the scalenus between the thumb and fingers (Fig. 25-58). Reproduction of shoulder or upper arm pain is positive for mechanical cervical lesions (Table 25-14), or a thoracic outlet dysfunction.[188]

Cervical Hyperflexion

The patient is positioned in sitting and is asked to flex his or her neck to the first point of pain or toward end range if no pain exists (Fig. 25-59). Reproduction of radicular symptoms during hyperflexion is considered a positive response (Table 25-14).

Cervical Hyperextension (Jackson's Test)

The patient is positioned in sitting and is asked to extend his or her neck to the first point of pain or toward the end range if no pain exists (Fig. 25-60). Reproduction of symptoms is considered a positive response (Table 25-14).

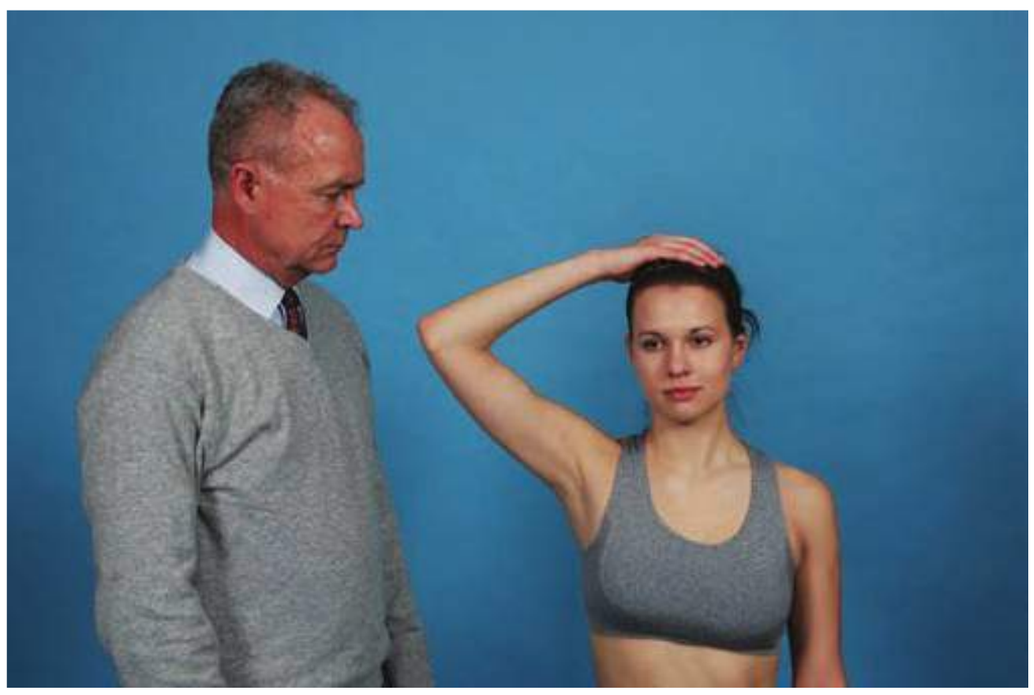

FIGURE 25-57 Shoulder abduction test.

FIGURE 25-58 Brachial plexus compression test without the side bending.

FIGURE 25-59 Cervical hyperflexion.

Cervical Distraction

The patient is positioned in supine. Using one hand, the clinician uses a lumbrical grip around the occiput. Using the other hand, the clinician wraps the hand gently around the patient's chin. A traction force is applied, and the patient's symptoms are assessed (Fig. 25-61). A positive test is a reduction of symptoms by the distraction and is indicative of some form of foraminal compression, or zygapophyseal joint irritation. This test appears to have high specificity but low sensitivity (Table 25-14).

Brachial Plexus Tests

Stretch Test

The patient is positioned sitting or standing and is asked to raise the arm on the involved side (Fig. 25-62) and then to side bend the head to the uninvolved side. Pain and paresthesia along the involved arm are indicative of a brachial plexus irritation.

Cervical Rotation Lateral Flexion Test

This test is used as part of the examination of a patient presenting with brachialgia and thoracic outlet symptoms to assess first rib hypomobility. The motion of cervical rotation combined with lateral flexion (side bending) can be restricted in the presence of a subluxed first rib at the costotransverse joint.[189] The patient is seated and the cervical spine positioned in neutral with regard to flexion–extension. The clinician then passively rotates the cervical spine maximally, away from the side to be tested, and then flexes the neck forward as far as possible, moving the ear toward the chest (Fig. 25-63). The test is then repeated on the other side, and a comparison is made about the quantity and quality of motion. If the first rib is subluxed, the restriction to passive movement is felt abruptly. If the restricted motion is found on one side, first-rib mobilizations are performed and then the patient is retested. Lindgren et al. found this test to have excellent interobserver repeatability and to have good agreement with a radiologic examination in the detection of a subluxed first rib.[190] However it is worth remembering that a number of additional factors may influence the finding, including TOS, cervical radiculopathy, and upper thoracic pain.

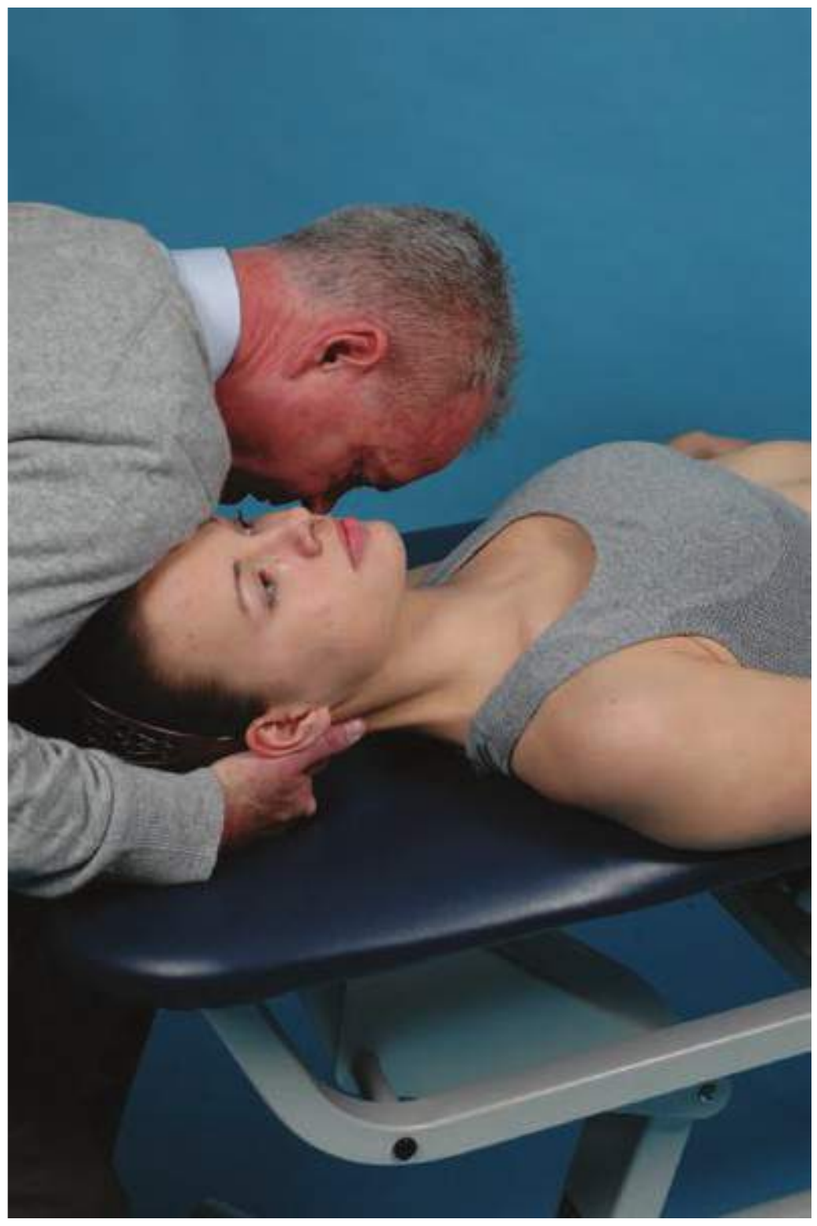

FIGURE 25-61 Cervical distraction.

FIGURE 25-60 Cervical hyperextension (Jackson's test).

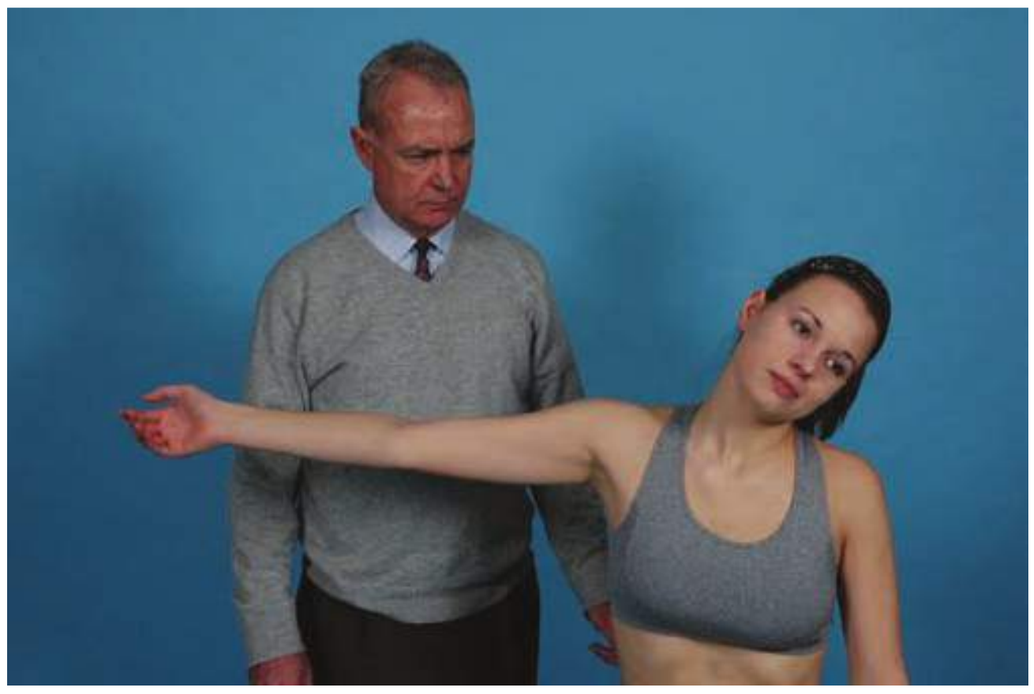

FIGURE 25-62 Stretch test.

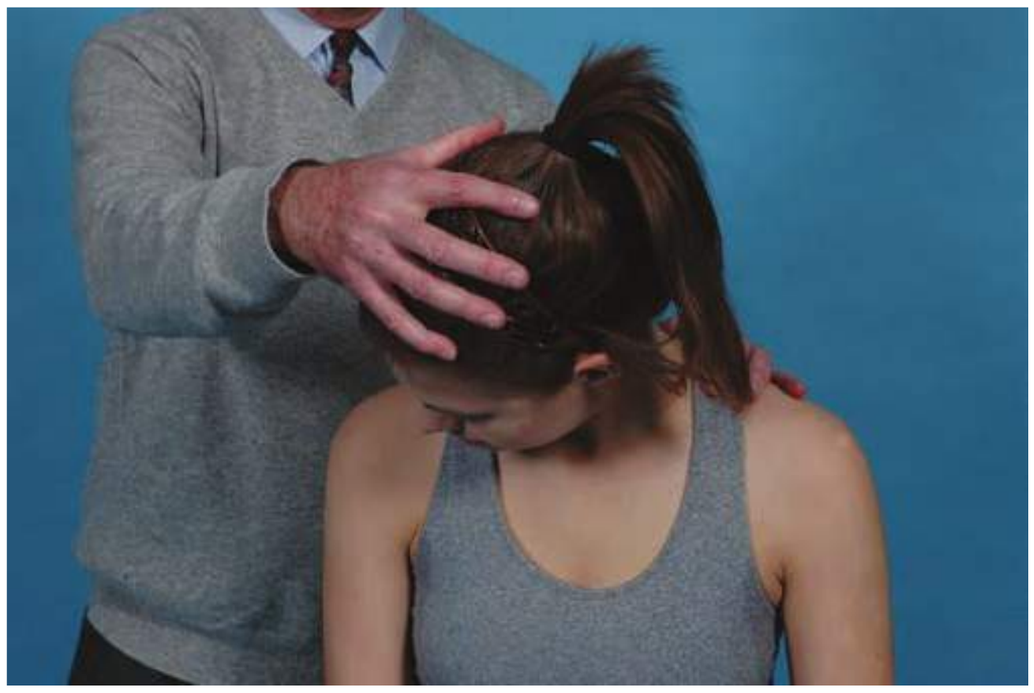

FIGURE 25-63 Cervical rotation lateral flexion test.

Tinel's Sign

The patient is positioned in sitting and is asked to side bend the head to the uninvolved side. The clinician taps or squeezes along the trunks of the brachial plexus using the fingers (Fig. 25-64). Local pain indicates a cervical plexus lesion. A tingling sensation in the distribution of one of the trunks may indicate a compression or neuroma of one or more trunks of the brachial plexus.[191]

Thoracic Outlet Tests

Despite their widespread use, no studies documenting the reliability of the common thoracic outlet maneuvers of Adson's, Allen's, or the costoclavicular maneuver have been performed.[192] Because TOS is a controversial diagnosis, most of the thoracic outlet tests examine specificity only.

When performing TOS tests, either the diminution or disappearance of pulse or reproduction of neurologic symptoms indicates a positive test. However, the aim of the tests should be to reproduce the patient's symptoms rather than just to obliterate the radial pulse.

FIGURE 25-64 Tinel's sign.

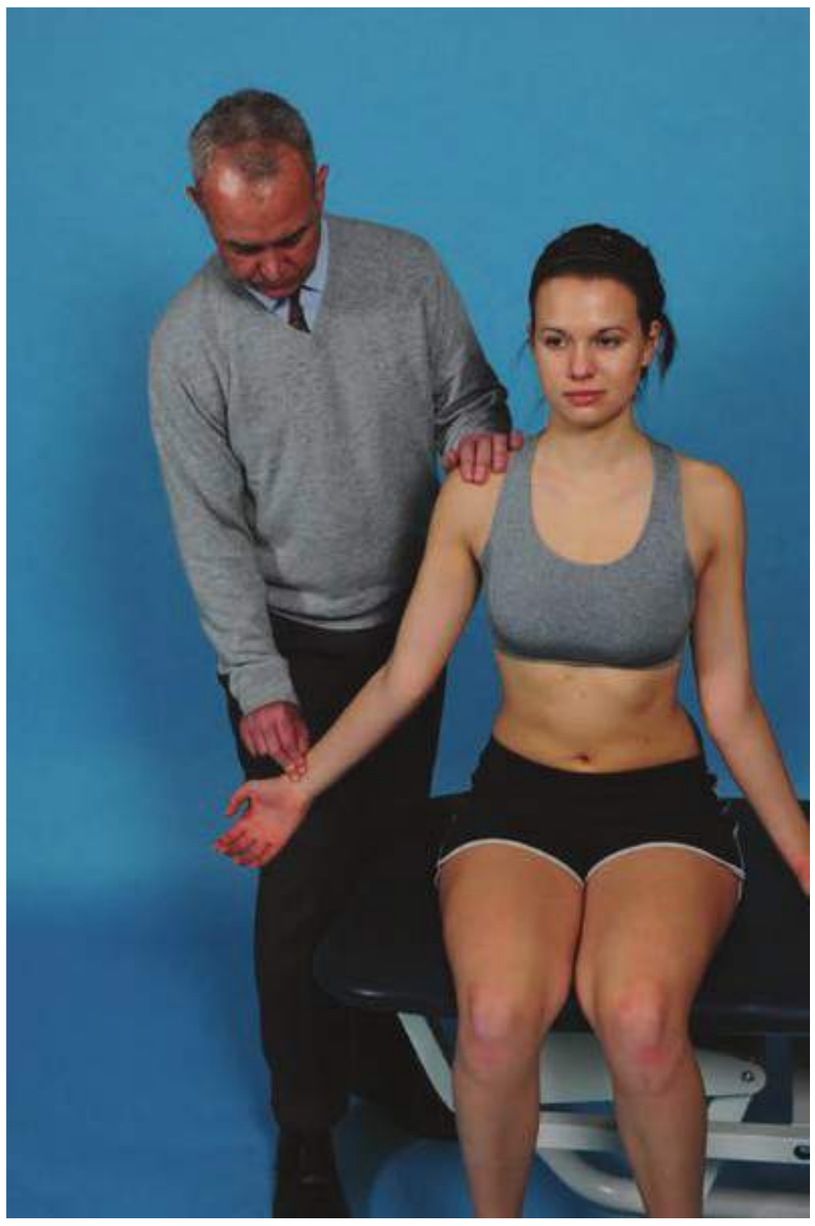

FIGURE 25-65 Adson's test.

Adson's Vascular Test

The patient is positioned in sitting with the arms placed at 15 degrees of abduction. The clinician palpates the radial pulse. The patient is asked to inhale deeply, and to hold his or her breath (Fig. 25-65). The patient is then asked to tilt the head back, and rotate the head so that the chin is elevated and pointed toward the examined side VIDEO. The clinician records the radial pulse as diminished or occluded and asks the patient about the presence of paresthesia. The test position theoretically increases the scalenus angle and the tension of the anterior and middle scalenes, thereby compromising the interscalene triangle.[193] However, biomechanically, the scalene angle actually increases, which should reduce the likelihood of compression. Moreover, to date, no studies have been performed to document the reliability of this test. Plewa and Delinger[194] found the specificity of this test to be 100% when assessing pain, 89% when assessing vascular changes, and 89% when assessing paresthesia.

Costoclavicular Test

The patient is positioned sitting straight in an exaggerated military posture and with both arms at the sides. The clinician assesses the radial pulse in this position. The patient is asked to retract and depress the shoulders while protruding the chest (Fig. 25-66) VIDEO. This position is held for 60 seconds. The clinician assesses changes in the radial pulse and asks the patient about the presence of paresthesia. It is likely that this test position reduces the volume of the costoclavicular space. Plewa and Delinger[192] found the specificity of this test to be 100% when assessing pain, 89% when assessing vascular changes, and 85% when assessing paresthesia.

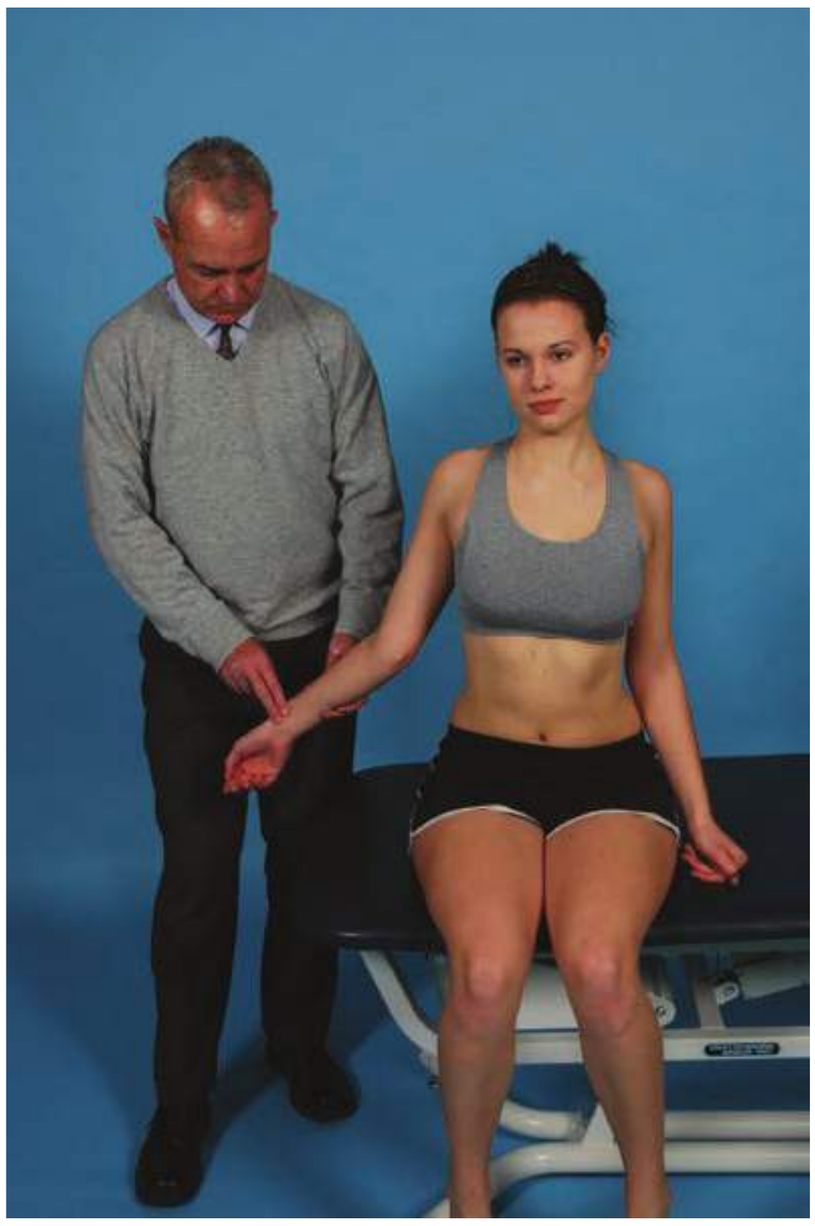

FIGURE 25-66 Costoclavicular test.

Roos Test

T e patient is positioned sitting. T e arm is positioned in 90 degrees of shoulder abduction and 90 degrees of elbow flexion. T e patient is asked to perform slow finger clenching for 3 minutes (Fig. 25-67). T e radial pulse may be reduced or obliterated during this maneuver, and an infraclavicular bruit may be heard. If the patient is unable to maintain the arms in the start position for 3 minutes, or reports pain, heaviness, or numbness and tingling, the test is considered positive for TOS on the involved side.[195] T is test is also referred to as the hands-up test, or the elevated arm stress test. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Hyperabduction Maneuver (Wright Test)

T e patient is positioned in relaxed sitting. T e clinician palpates the radial pulse and then asks the patient to raise his or her shoulder or to abduct the arm and to turn the head away from the side being examined (Fig. 25-68). T e position is held for 1–2 minutes. A positive test includes a reproduction of paresthesia or a decrease in the radial pulse.[196] No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test. However, note that a number of studies have found that these positions induce radial pulse obliteration in 60–69% of normal subjects.[197,198]

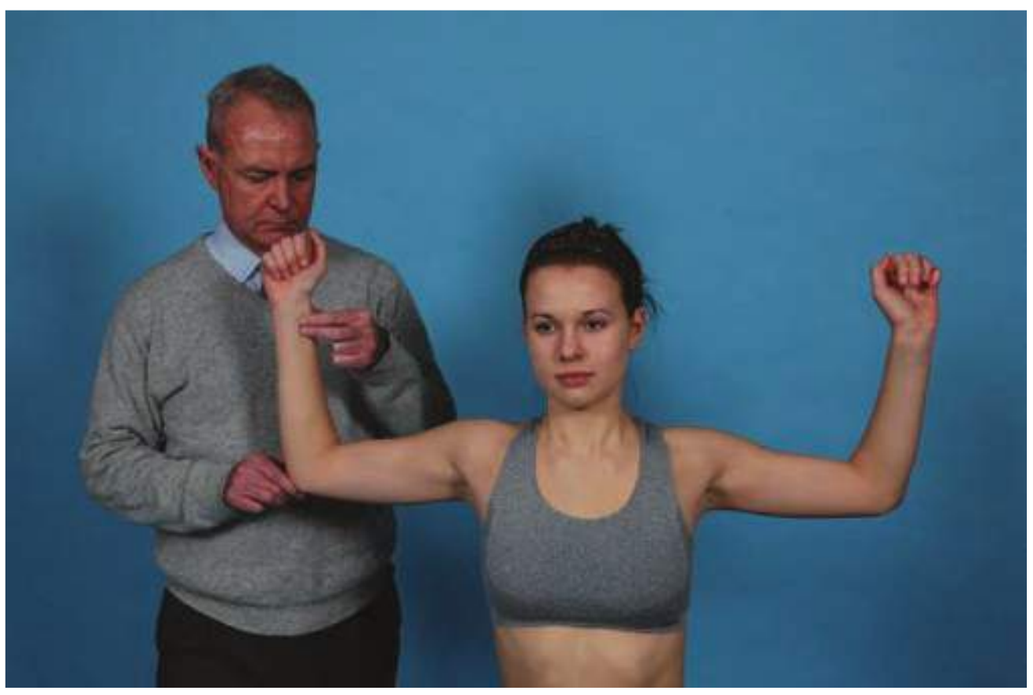

FIGURE 25-67 Roos test.

FIGURE 25-68 Hyperabduction maneuver (Wright test).

Passive Shoulder Shrug

T is simple, but effective, test is used with patients who present with symptoms of TOS to help rule out this syndrome. T e patient is seated with the arms folded, and the clinician stands behind. T e clinician grasps the patient's elbows and passively elevates the shoulders up and forward (Fig. 25-69). T is position is maintained for 30 seconds. Any changes in the patient's symptoms are noted. T e maneuver has the effect of slackening the sot tissues and the brachial plexus. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

UPPER LIMB TENSION TESTS

T e reader is encouraged to refer to Chapter 11 for the descriptions of these tests. T e upper limb tension tests are equivalent to the straight leg raise test and others of the lower extremities and are designed to put stress on the neuromeningeal structures of the upper limb. A negative finding strongly suggests a lack of existence of radiculopathy (Table 25-15). Each test begins by testing the normal side first. Normal responses include the following:

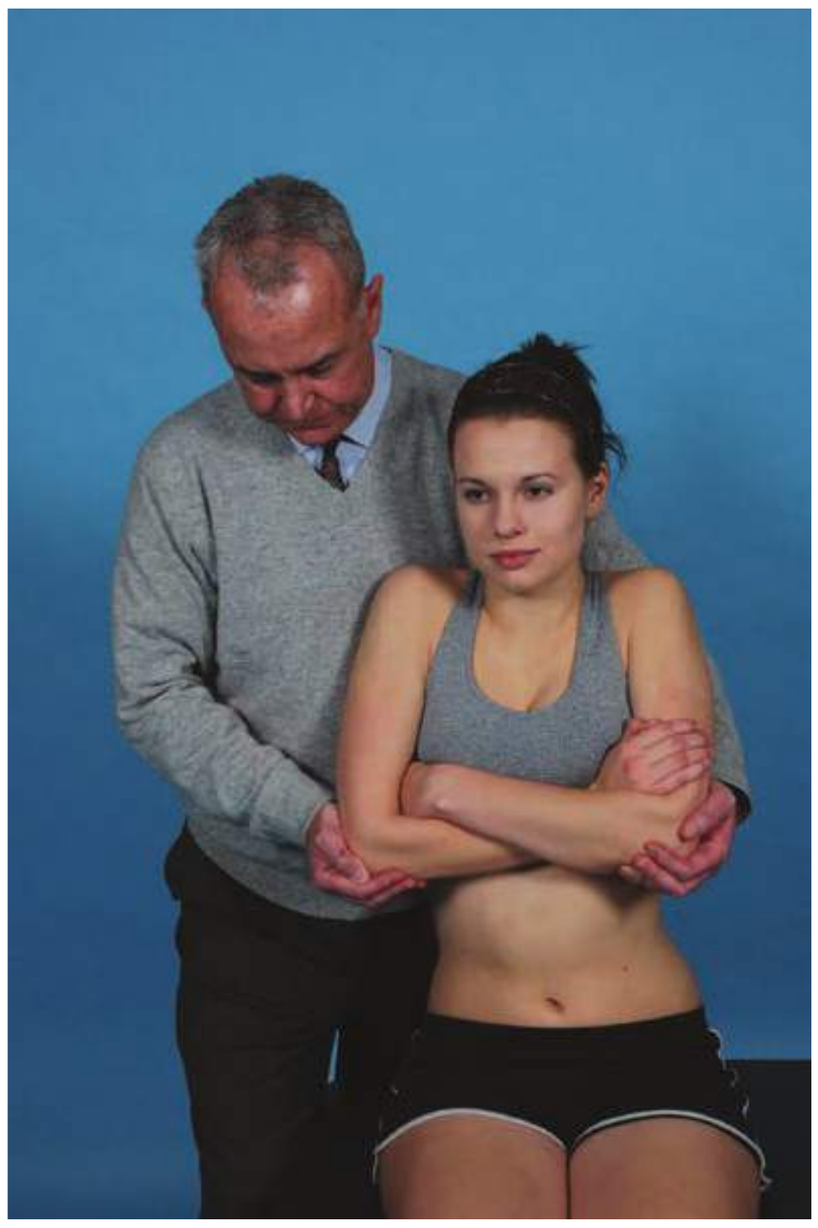

FIGURE 25-69 Passive shoulder shrug.

- Deep stretch or ache in the cubital fossa;
- Deep stretch or ache into the anterior or radial aspect of the forearm and radial aspect of hand;
- Deep stretch in the anterior shoulder area;
- A sensation felt down the radial aspect of the forearm; and
- A sensation felt in the median distribution of the hand.

Positive findings include

- Reproduction of the patient's symptoms; and
- A sensitizing test in the ipsilateral quadrant that alters the symptoms.

IMAGING STUDIES

It is recommended that the results of any imaging studies should be viewed after the clinical examination, so as to remove the potential for bias, especially in light of the fact that degenerative changes and anatomical variations are fairly common in the cervical spine, but that many of these changes have no relationship to the patient's complaints. A description of the various imaging studies and their relevance to a specific region is given in Chapter 7.

INTERVENTION STRATEGIES

Patients with neck pain account for 25% of all outpatient physical therapy visits.[199] Cervical impairments have the same causes as any other areas of the body, that is, a micro- or macrotraumatic impairment of the structures that compose the joint complex.

The clinician must discuss the diagnosis, prognosis, and the intervention with the patient. It is important that the clinician describe the basic anatomy and function of the cervical spine in a way that the patient will understand. Expectations of both the patient and the clinician must be clarified. Patients must realize at the outset that they are responsible for their own recovery and must participate actively in their treatment.

Based on a working hypothesis, the physical therapy intervention needs to be precise and guided by the impairments, functional limitations, and disability found during the examination. The intervention should aim to reverse the dysfunction and to prevent the recurrence of future episodes. A study by Saturno et al.,[200] which assessed the reliability and validity of existing clinical guidelines on neck physiotherapy treatment and follow-up in Spain, determined the eight evidence-based recommendations listed in Table 25-16. Other studies have reported that physical therapy interventions that have included manual therapy, postural reeducation, neck-specific strengthening and stretching exercises, and ergonomic changes at work have been shown to be beneficial in reducing neck pain and improving mobility.[201–203] A pragmatic randomized clinical trial by Hoving et al.,[204] which compared the effectiveness of manual therapy (mainly spinal mobilizations), physical therapy (mainly exercise therapy), and continued care by the general practitioner (analgesics, counseling, and education) for cervical pain over a period of 1 year, found high improvement scores for the manual therapy group for all the outcomes, followed by physical therapy and general practitioner care.

The joint mobilization techniques for the cervical spine and the manual techniques to increase soft tissue extensibility are described later, under section "Therapeutic Techniques."

Systematic reviews of physical therapy modalities for neck pain report a lack of high-quality evidence of their efficacy and highlight poor methodologic quality in many studies.[205] Electrotherapy has a long history of use in physical therapy interventions, and two high-quality trials reported that pulsed shortwave diathermy delivered by small portable units

TABLE 25-15 Clinical Usefulness of Upper Limb Tension Tests

Test	Reliability	Sensitivity	Specificity	LR+	LR–	DOR	QUADAS Score

TABLE 25-16 Evidence-Based Recommendations for Cervical Intervention

Every patient with neck pain must receive ergonomic advice on the reduction of repetitive movements and/or postures. As a basic treatment for all patients, an active physical therapy program will be useful in neck and shoulder muscles. This will include

1. active stretching exercises;
2. dynamic muscular strengthening exercises; and
3. exercises to do at home.

As a basic treatment for all patients with chronic neck pain (>3 months) a program of oculocervicokinetic reeducation (exercises to address eye–head coordination to improve cervicocephalic anesthesia—the ability to relocate accurately the head on the trunk after an active movement in the horizontal plane) will be used.

If trigger points are identified in some muscles, transcutaneous electrostimulation will be used.

If there is a dysfunction of the analytic joint passive mobility, joint mobilization/manipulative treatment will be used, which includes structural techniques of vertebral mobilization/manipulation, or contract–relax techniques, or both.

If there is pain radiating to the upper limb, mechanical intermittent cervical traction will be used.

inserted into cervical collars significantly reduced pain in patients with mechanical neck pain.[202,206]

Acute Phase

During the acute phase, the patient should be encouraged to perform as many activities of daily living as possible. The return to activities should be encouraged and begin within 2–4 days after a cervical injury, depending on severity. Rest is usually advocated in the first 24–72 hours, depending on the severity of the injury, to give healing a chance. Indications for rest include pain reported with all neck and head motions, however, slight, and high irritability of the symptoms. Ignoring the need for rest in these situations increases the risk of delaying the recovery from the acute phase. In those situations where absolute rest is warranted, the patient is told that rest means just that. Pillows should be adjusted so that the head remains in neutral when sleeping in side-lying or supine position. The patient should be cautioned about prone lying.

Patients are encouraged to take up or resume a regular activity such as walking or, later in this phase, swimming and perhaps running, or anything else that will get them back to a normal mind set about their function, without reinjuring the area.

In general, two basic approaches are used to treat neck pain with exercises:

- General strengthening and endurance exercises for the neck flexor muscles.[207,208]
- Specific exercises designed to improve coordination and control of the muscles.[79]

Appropriate exercises must ensure proper motor control, performance, and endurance of a specific part of the body. When prescribing exercises to the patient, the clinician must decide on the type of muscle contraction, the patient's body position, the level of resistance or load, and the number of repetitions, and method of progression.[209,210] Gentle exercises are prescribed in the first part of the healing phase. The main reasons for these early exercises are as follows:

- To encourage patient involvement;
- To provide mechanoreceptor stimulation;
- To control pain and inflammation;
- To promote healing;
- To maintain the newly attained ranges; and
- To provide neuromuscular feedback.

CLINICAL PEARL

Considerable evidence has recently been identified indicating the effectiveness of high-velocity thrust manipulations in patients with acute and subacute neck pain in both the short and long term.[211–213] A randomized clinical trial by Dunning et al.[214] concluded that a combination of upper cervical and upper thoracic high-velocity thrust manipulation was appreciably more effective in the short term than nonthrust mobilization in patients with mechanical neck pain. However, the benefits in this study were only measured for the first 48 hours after treatment. A randomized clinical trial by Masaracchio et al.[215] reported that individuals with neck pain who received a combination of thoracic spine thrust manipulation and cervical spine and nonthrust manipulation plus exercise demonstrated better overall short-term outcomes on the numeric pain rating scale, the NDI, and the global rating of change.

AAROM/AROM

The patient is positioned in supine with the head supported on a pillow or a towel roll. Usually, the easiest and most comfortable exercise is rotation. The patient is asked to perform gentle, active, small-range, and amplitude rotational movements of the neck, initially in one direction, and then the other up to a maximum range of comfort.[216] Care must be taken with these exercises to ensure that the normal movement pattern is performed and that the pattern is reinforced with repetition. The movements are repeated 10 times in each direction. According to Bird et al.,[217] to improve endurance, a repetition of 4–6 sets per exercise, with rest periods of 30–60 seconds between sets, is appropriate. To help relieve muscle

tension, the exercises can be done in conjunction with breathing.[95] When the patient reaches the end of the comfortable range (at the point where some tissue resistance is first being felt), the patient takes a moderate breath in and then releases it. At the end of the release, a relaxation of the muscles allows a slight increase in range without stressing any tissues, and without causing pain. T e focus of these exercises is on motor control rather the muscle strength.

Once these non–weight-bearing, active, assisted range-of-motion exercises can be performed without an exacerbation or recurrence of symptoms, active CROM exercises can be initiated in the sitting, and then standing positions.

Retraining of Craniovertebral Flexion

T e patient is positioned in supine and is instructed by the clinician on how to perform correct craniovertebral flexion (CVF) using gentle nodding movements while eliminating any compensation strategies, such as neck retraction, excessive cervical flexion, and/or jaw clenching.[79]

Head Nod. T e key exercise to recruit the deep cervical flexors, which are the most common muscles to become weak with neck dysfunction, is the head nod exercise (Fig. 25-70).[216] Correct performance of the exercise ensures that the flexion only occurs at the junction between the head and neck (at the O-A joint) before continuing segmentally into midcervical flexion. T e exercise is initially performed in sitting or supine, while ensuring that no forward movement of the head occurs (which would change the exercise into one of eccentric contraction of the cervical extensors). T e patient can be taught to palpate the SCM and scalene muscles during the exercise for any unwanted contractions. As the patient gradually nods the chin down, the back of the head should be seen to move upwards. T e nod is stopped at the point in the range that can be achieved without superficial muscle activity, held for 10 seconds to promote the endurance function of the muscles, and is repeated 10 times. Once the patient is able to tolerate the exercise in the supine or upright position, they are asked to perform the exercise in supine on an inclined board (Fig. 25-71). As the inclined board is tilted progressively backward toward horizontal the assistance from gravity is gradually reduced.

FIGURE 25-71 Head nod on incline.

Once in supine, the head is positioned in neutral, either resting on a pillow, or on a small folded towel placed under the occiput so that the normal cervical lordosis is supported (Fig. 25-72). In this position, the head nod exercise is performed with no lit ing of the head from the surface, while the patient palpates anteriorly to ensure no superficial muscle activity. Once this is mastered, the exercise is progressed so that the head nod uses the towel roll as a fulcrum (making sure that the neck does not lose contact with the towel) and the back of the head may lit just off the bed during the motion, while preventing the chin from poking forward (this is a sign of excessive anterior translation caused by a relative dominance of the SCM and scalenes). At this time, it is no longer necessary to palpate the anterior structures as the superficial muscles must now be active to lit the head off the bed (Fig. 25-73). In the case of an asymmetric weakness, a head nod into a flexion quadrant (e.g., flexion, side bending, rotation to the same side) can be used to highlight contraction of the flexors more unilaterally. T e exercise can also be performed in prone over an exercise ball or in the quadruped position (Fig. 25-74). In the prone position, gravity draws the head forward into a position of upper cervical extension, which is opposed by the head nod motion into upper cervical flexion.

FIGURE 25-70 Head nod.

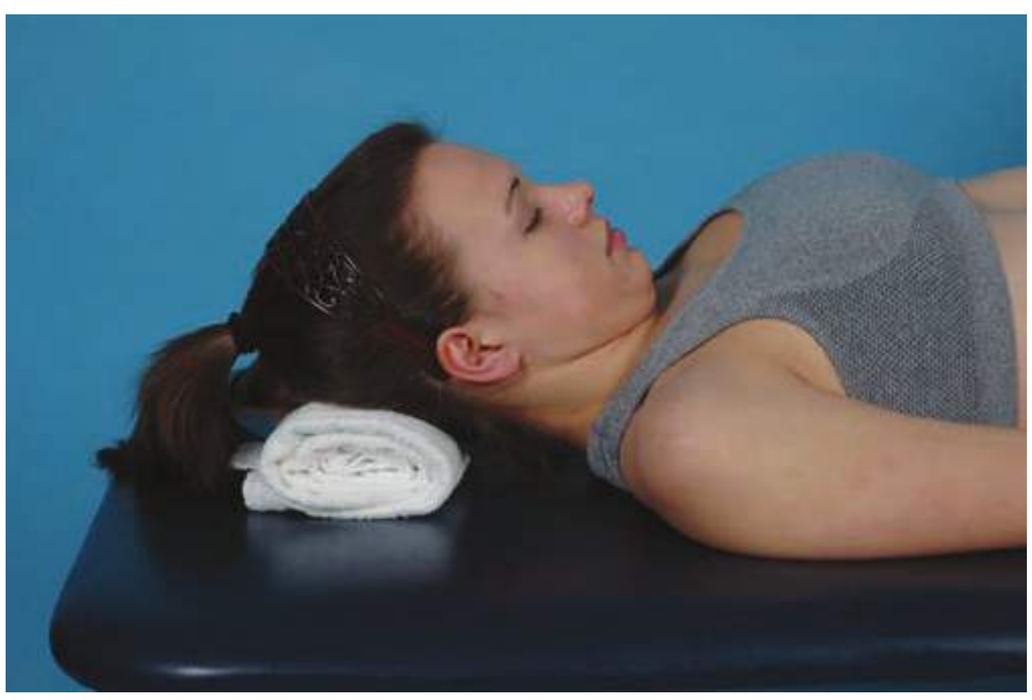

FIGURE 25-72 Head nod with towel roll in supine.

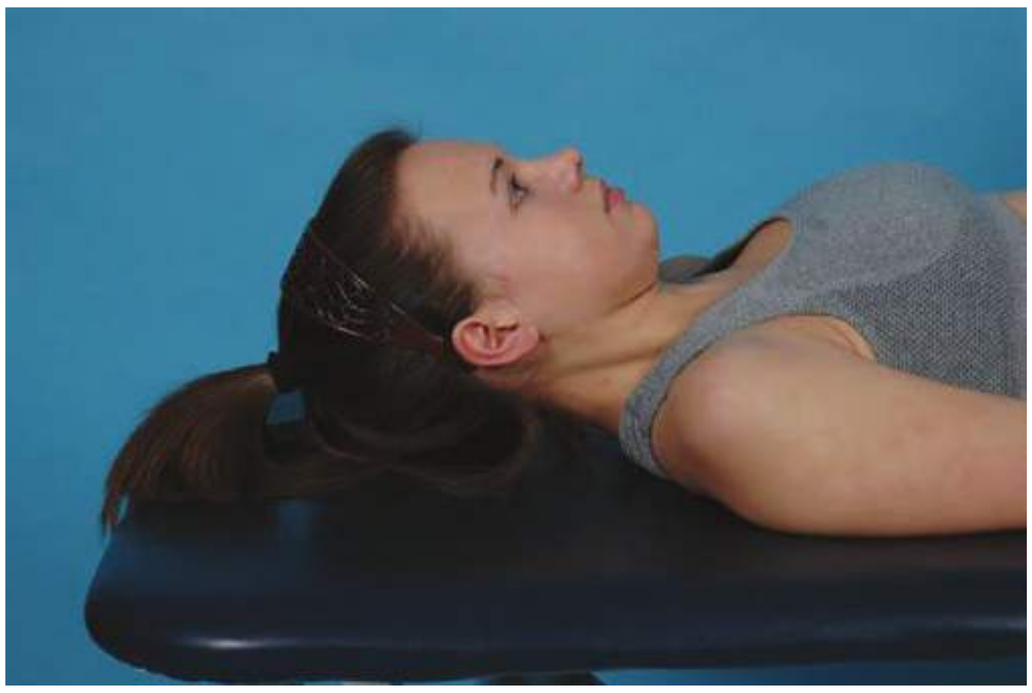

FIGURE 25-73 Head nod with head lift.

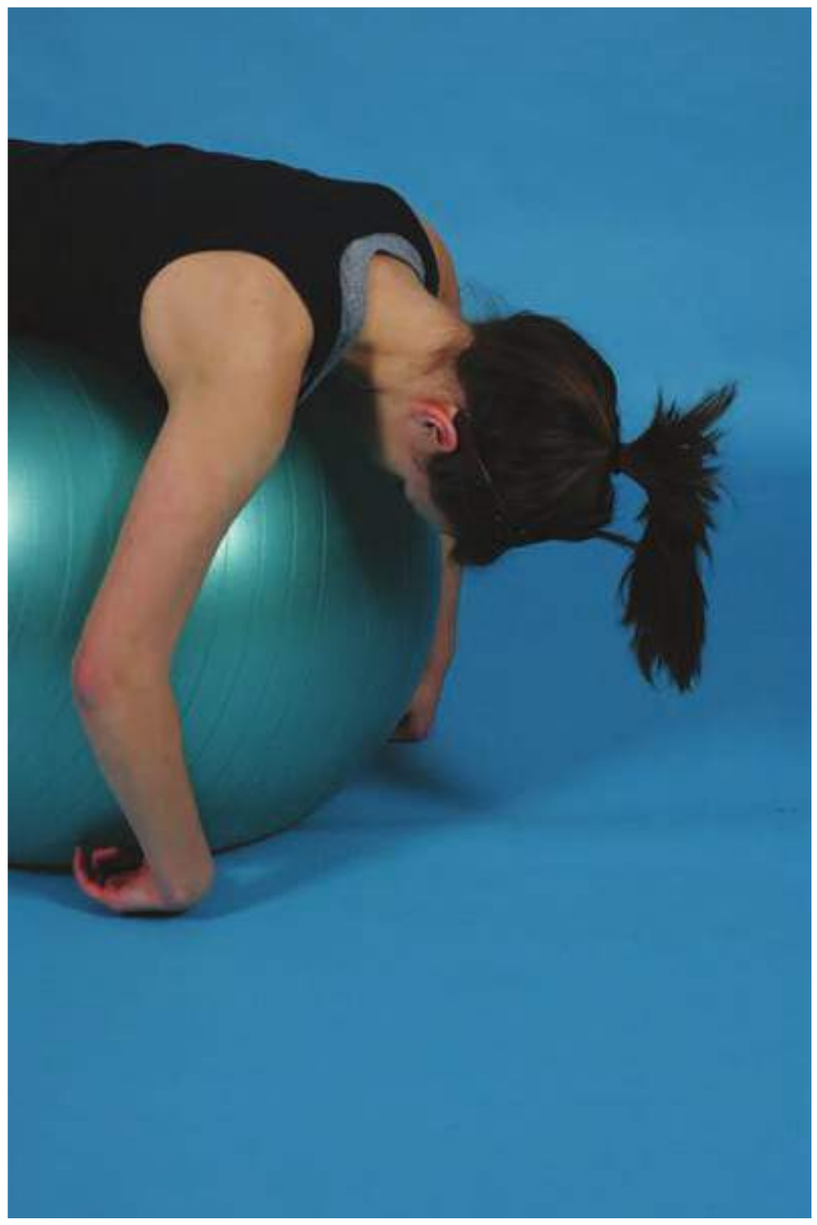

FIGURE 25-74 Head nod prone on Swissball.

Return to Neutral[216]

T e return to neutral exercise is intended to recruit the deep cervical segmental extensors. T e deep cervical extensor muscles include the semispinalis cervicalis and the multifidus. T e craniovertebral extensor muscles include the rectus capitis and the suboccipital muscles. While in the sitting position, and starting from a position at the end of the head nod exercise, the patient is asked to lit the chin gradually and then look up toward the ceiling (eccentric contraction of the cervical flexor muscles), while preventing any chin retraction or cervical retraction, and to continue this movement, trying to look farther along the ceiling, until the end of the comfortable range is reached. At this point, the patient then returns to the start position (a concentric contraction of the cervical flexor muscles). Once the patient is able to perform this exercise correctly, the start position is initiated from a position of CVF (Fig. 25-75). If the CV region can be sustained in flexion until the end of the motion, the capitis group of the erector spinae muscles will tend to be inhibited. T e exercise is progressed by having the patient perform it on all fours (Fig. 25-76). Finally, isometric hold exercises in different parts of the range

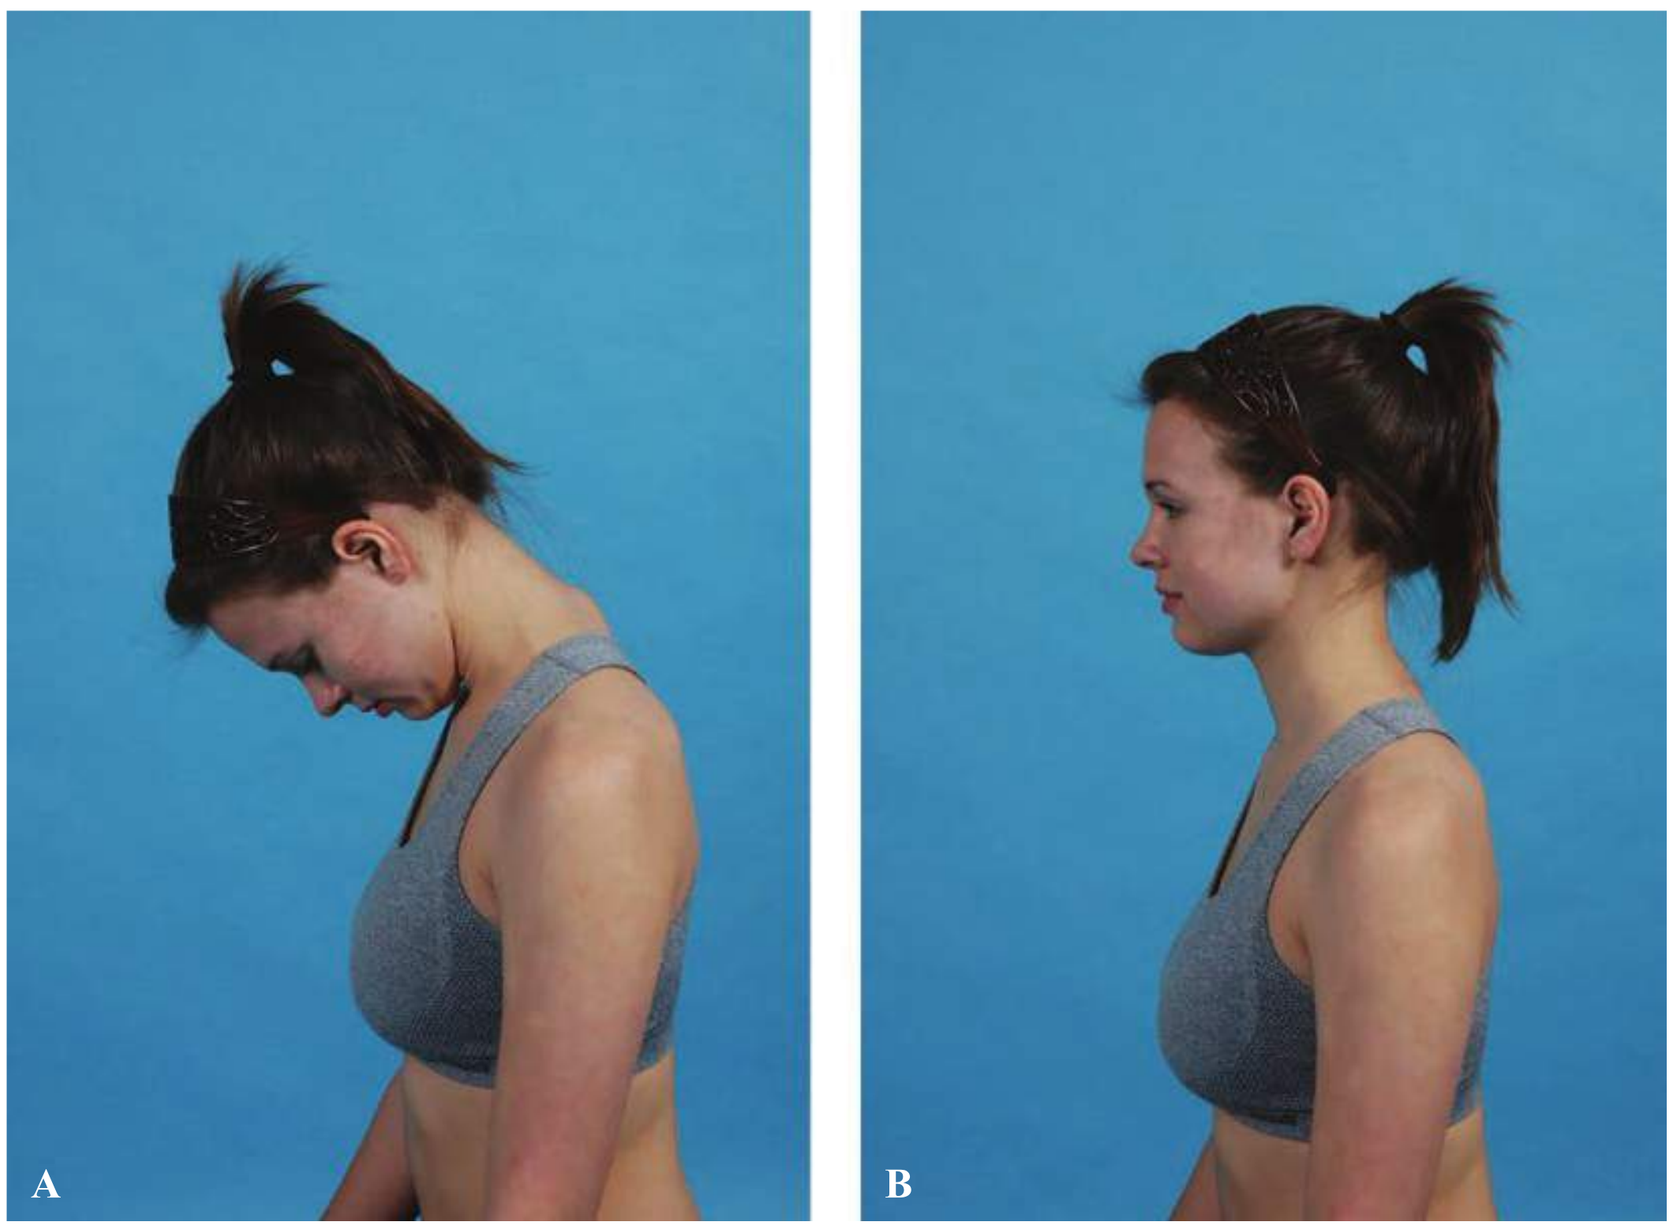

FIGURE 25-75 Seated head nod with return to neutral. A: Start position. B: End position.

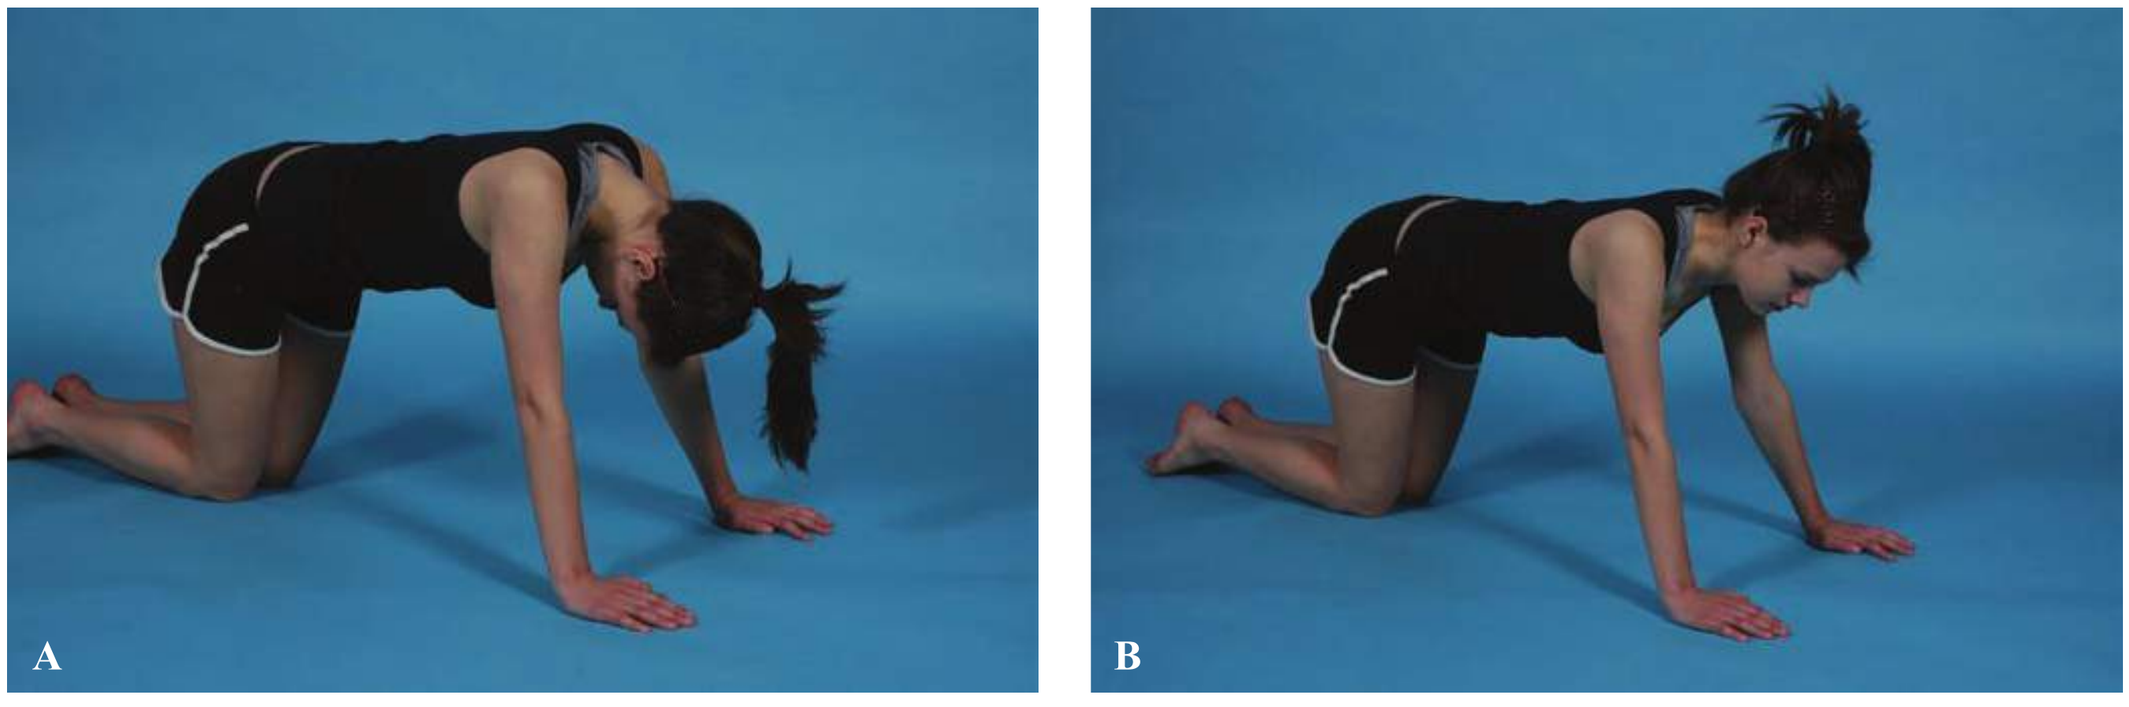

FIGURE 25-76 Return to neutral on all fours. A: Start position. B: End position.

can be initiated and progressed based on patient tolerance. In cases of asymmetric weakness, the exercise can be made more specific by working into an extension quadrant (e.g., combined extension, side bending, and rotation to the same side).

Coupling Activation[216]

The primary side benders and rotators can be recruited by exercising into a quadrant position. For both the following exercises, the patient is told to perform a preset nod to activate the deep stabilizing muscles before performing any motion of the head. These muscles can be trained more specifically and intensely in the side-lying position, with the head supported on a wedge (Fig. 25-77). As the head is lifted off the wedge, the muscles opposite to the side the patient is lying on contract against gravity. The deeper muscles can be emphasized by ensuring that the neck remains in contact with the wedge, thereby decreasing the amount of translation.

Global Strengthening

The global strengthening exercises are initiated with submaximal isometric contractions throughout the single planes using multiangle submaximal isometric contractions, including flexion VIDEO, extension VIDEO, side bending VIDEO, and rotation VIDEO (Fig. 25-78A-D). The manual resistance is initially applied by the clinician and then by the patient. Although these exercises should not cause sharp pain, they may produce mild delayed-onset muscle soreness. Minimal resistance is used in the neutral position to aid in venous return, stimulate the mechanoreceptors in the muscle, and allay any concerns regarding weakening of the neck from disuse or a cervical collar.[95]

The exercise progression proceeds using the following principles[218]:

- The hold time of the isometric contraction is increased.
- The number of repetitions of this holding activity is increased.
- Progression to the next level is based on the ability of the patient to stabilize and isolate the correct muscle action in the exercise positions.

FIGURE 25-77 Combined flexion, side bending, and rotation on wedge in side lying.

Increasing the Holding Capacity of the Deep Neck Flexors

Once the patient is able to perform a correct CVF movement, the emphasis switches to increasing the endurance capacity of the involved muscles (deep neck flexors). It is recommended that a preinflated, air-filled pressure sensor is used to help guide and control the training of these muscles so as to provide visual feedback and motivation to the patient.[79] The starting point for the training is the pressure level the patient has reached and can hold without compensation for at least 10 seconds (typically at 22 or 24 mmHg). The patient is instructed on how to achieve the determined pressure level and then to hold it for a time without evidence of compensation or poor motor patterns. The aim is to the patient to hold the position for 10 seconds and then to repeat this 10 times. Practice should occur at least twice a day. The goal is for the patient to perform this exercise with a pressure level between 28 and 30 mmHg. Depending on the patient, achievement of this goal can take anywhere from 4 to 6 weeks to 12 weeks.[79]

Co-contraction of the Neck Flexors and Extensors

These exercises are initially performed with the patient positioned in sitting, and consist of a series of gentle, alternating self-resisted isometric rotation contractions, similar to those used with rhythmic stabilization protocols. A typical progression for training the cervical flexors and extensors to enhance dynamic stability is outlined in Table 25-17.

FIGURE 25-78 Cervical submaximal isometrics in four planes. A: Flexion. B: Extension. C: Rotation. D: Side bending.

The other exercises prescribed early in the intervention include the following:

- Exercises designed to regain correct scapular positioning. In patients with cervical problems, the scapula is typically protracted and downwardly rotated. Exercises are prescribed in an attempt to bring the coracoid upward and the acromion backward incorporating a slight retraction and lateral rotation of the scapula. Exercises include shoulder shrugging VIDEO and shoulder square (retraction) exercises VIDEO. The scapula retraction exercises are initially performed supine, with the glenohumeral joint in internal and external rotation. The patient is asked to retract the shoulders isometrically against the bed.
- Exercises designed to increase the endurance capacity of the scapular stabilizers, and scapular control with arm movements and loads (see Chapter 16).

TABLE 25-17 Retraining Progression for the Cervical Flexors and Extensors

Exercise	Patient Position	Description
Cervical bracing	Four-point kneeling	The patient is asked to protract the head and then to perform upper cervical flexion while maintaining the lower cervical spine in a neutral position. This position is held for at least 10 seconds.
Cervical bracing with extremity movements	Four-point kneeling	The patient is asked to combine cervical bracing with arm and leg movements. While maintaining the stability of the body and cervicothoracic region, the patient raises an arm. The patient then raises a leg. These movements are alternated (right arm, left leg; right leg, left arm) until the patient can maintain them and perform the correct movement pattern. To provide more challenge, the patient can be asked to balance a light book on the head.
Cervical bracing with extremity movements on unstable base	Push-up position with lower legs on a Swiss ball	The patient is asked to combine cervical bracing while balancing on a Swiss ball.

Data from Murphy DR. Conservative Management of Cervical Spine Syndromes. New York, NY: McGraw-Hill; 2000; O'Grady WH, Tollan MF. The role of exercise in treating cervical hypermobility or instability. Orthop Phys Ther Clin North Am. 2001;10:475–501.

- For nerve irritation hip and knee flexion–extension exercises and ankle dorsiflexion in non–weight-bearing position (to help move the dura).
- Isometric, shoulder and abdominal exercises (using the Valsalva maneuver, not pelvic tilting or sit-ups).
- Postural reeducation.

As with any exercise progression, these exercises are replaced with more challenging exercises, as the patient's healing progresses. Guidelines are provided for safe home exercising by teaching the patient to identify warning signs that could lead to exacerbation or recurrence of symptoms. In the event of an increase in symptoms, the techniques are adjusted by reducing either the amplitude of the movements or the number of movements, or both.

Other movements, such as cervical retraction VIDEO and cervical protrusion, can be added to the program, depending on which movements are found to be beneficial during the progression.

The efficacy of electrotherapeutic modalities has not been subjected to randomized clinical trials.[219] Although passive modalities have their uses in the acute phase, the clinician should remember that they must only be used as an adjunct to the more active program, and with a specific goal in mind, such as to help in the reduction of pain and inflammation. Thus, the patient should be weaned from the use of modalities as early as possible. Cervical traction (see Chapter 8) has been advocated for neck sprains, and for the pain of radiculopathy, but no clinical or statistically significant change in pain or overall range of motion has been identified.[220–223]

- Ultrasound. Pulsed ultrasound should be used precisely.[224] It can be applied to the posterior aspects of the zygapophyseal joints to control pain and reduce swelling or to a torn muscle.
- Nonthermal agents. Theoretically, ice is the preferred choice during this phase. However, ice can often increase the pain that arises from trigger points. At the earliest opportunity, the application of heat is introduced because of its ability to relax musculature and stimulate vasodilation.[225]
- Electrical muscle stimulation.[95] Providing that none of the muscles stimulated are torn, electrical muscle stimulation can be used in the early stages as an effective pain reliever and as a venous pump. The patient is positioned supine. A small electrode is placed on each of the left and right suboccipital muscles, and a large common electrode is placed along the upper thoracic spinous processes. The channels are made to stimulate asynchronously with a long "on" ramp, and a contraction length of 2 or 3 seconds (certainly no longer than 5, because this becomes uncomfortable). The session can last anywhere from a few minutes to 30 minutes once it is established that there are no adverse effects of the intervention.

Numerous manual therapy techniques are available to the clinician, each with its own uses. These techniques, described later under section "Therapeutic Techniques," can be used with hypomobilities and soft tissue injuries. The nature and location of the dysfunction, as well as the intention of its effect, guide the selection of a particular technique. Movement gained by a manual technique must be reinforced by both the mechanical and neurophysical benefits of active movement.[69]

No randomized controlled trials (RCTs) have been done on the efficacy of manipulations for patients with predominantly acute neck pain. A number of RCT studies have been done with subacute and chronic neck pain, most of which have shown that manipulation is probably slightly more effective than mobilization or other interventions.[226]

Cervical Collars

The use of cervical collars is controversial. Although several studies have concluded that the wearing of a cervical collar results in delayed recovery, these studies looked at the use of collars and other passive therapies versus other more active forms of intervention, such as early patient activation and exercise. A study by Mealy et al.[227] found that early active mobilization techniques following a WAD improved pain reduction and increased mobility, compared with a control group receiving 2 weeks' rest with a soft cervical collar and gradual mobilization thereafter. Another study[228] found physical therapy or exact instructions in a home program of self-mobilization to be better than 2 weeks' rest, with a soft collar at the 1- and 2-month follow-ups. A similar result was found at the 2-year follow-up.[229] Borchgrevink et al.[230] found that patients encouraged to continue with daily activities had a better outcome than patients prescribed sick leave and immobilization.

With those patients who have a severe capsular restriction of motion, however, a cervical collar should be issued. Soft cervical collars do not rigidly immobilize the cervical spine and if used judiciously can provide support for the head and neck in the very acute stages.[219,231]

The collar serves a number of functions as follows:

- Providing support in maintaining the cervical spine erect;
- Reminding the patient that the neck is injured and, thereby, preventing the patient from engaging in unexpected or excessive movements;
- Allowing the patient to rest the chin during activities, thereby offsetting the weight of the head;
- Allowing the patient to perform cervical rotations while the weight of the head is offset.

Prolonged reliance on the use of a collar may induce stiffness and weakness, but this can be avoided by recommending a time-limited use of the collar, which is based on specific factors such as the patient's condition and function. Certain situations warrant the use of a collar, such as long drives in a vehicle or prolonged postures of standing and sitting. However, patients should be weaned off the collar once there is a significant improvement in the range of motion and pain levels.

Functional Phase

Although strengthening exercises have been advocated for the intervention of neck pain,[207,232] only a few controlled intervention studies have been conducted to examine their benefit.

However, in one randomized study, investigators found that a multimodal intervention of postural, manual, psychological, relaxation, and visual training techniques was superior to traditional approaches involving ultrasound and electric stimulation.[233] Patients returned to work earlier, and they had better results in pain intensity, emotional response, and postural disturbances.[233]

T e stabilization of this region must include postural stabilization retraining of the entire spine.

Cervicothoracic stabilization is a specific type of therapeutic exercise that can help the patient to (1) gain dynamic control of cervicothoracic spine forces, (2) eliminate repetitive injury to the motion segments, (3) encourage healing of the injured segment, and (4) possibly alter the degenerative process.[234]

Cervicothoracic stabilization exercises include the following:

Shoulder Shrugs with Resistance

T ese exercises, initiated in the acute phase without resistance, are progressed so that the patient performs them with resistance added by asking the patient to hold a weight in each hand. T e shrug strengthens the upper trapezius, levator scapulae, and rhomboids. T e shoulder circles strengthen the upper trapezius, levator scapulae, and rhomboids.

Scapular Retraction

Once this exercise can be performed in supine without pain, the patient performs the exercise in the side-lying position and then prone or standing without resistance VIDEO. Resistance is added as tolerated. Scapular retraction in internal rotation of the glenohumeral joint strengthens the infraspinatus, teres minor, middle and posterior deltoids, and the rhomboids. Scapular retraction in external rotation of the glenohumeral joint strengthens the infraspinatus, teres minor, middle and posterior deltoids, and middle trapezius VIDEO.

Serratus Punch

T is exercise is performed initially with the patient supine, one shoulder flexed to 90 degrees, and the elbow extended. From this position, the patient raises the extended arm toward the ceiling and protracts the shoulder girdle. T is exercise can be progressed by adding a weight to the hand and performing it against a wall or a chair, before progressing to a push-up on the floor.

Tree Hug

T e patient is asked to wrap a length of elastic tubing around the back and to hold the two ends, with the thumbs pointing forward and the arms in about 60 degrees of abduction (Fig. 25-79). From this position, the patient is asked to imagine hugging a tree and to reproduce that motion.

Upright Rows Video

T e muscles involved with this exercise (Fig. 25-80) include the deltoids, supraspinatus, clavicular portion of the pectoralis major, long head of the biceps, upper and lower portions of the trapezius, levator scapulae, and serratus anterior.

FIGURE 25-79 Tree hug.

Elastic tubing is placed under the feet, and the ends are held in each hand. Keeping the back straight and the elbows out to the side, the patient raises his or her hands from about waist height to just below the chin (Fig. 25-80).

FIGURE 25-80 Upright rows.

FIGURE 25-81 Lateral arm raise.

Lateral Arm Raise

T is exercise (Fig. 25-81) is initiated without resistance. Once it can be performed without pain, resistance in the form of tubing or hand weights is added. Lateral arm raises involve the deltoid, supraspinatus, serratus anterior, and upper and lower trapezius.

Front Arm Raise

Again, this exercise (Fig. 25-82) is initiated without resistance. Once it can be performed without pain, resistance in the form of tubing or hand weights is added. Front arm raises involve the anterior deltoid, pectoralis major (upper portion), coracobrachialis, serratus anterior, and upper and lower trapezius.

Cervical Retraction Against Gravity

To strengthen the cervicothoracic stabilizers, the patient is positioned prone, with the head off the end of the bed and supported in a protracted position of the neck. T e patient is asked to retract the chin from this position, raising the head toward the ceiling, while maintaining the face parallel to the floor (see Fig. 25-14).

Gravity Cervical Stabilization

T ese exercises can be performed into extension, rotation VIDEO, and side bending VIDEO. Cervical side translations can also be performed against gravity.

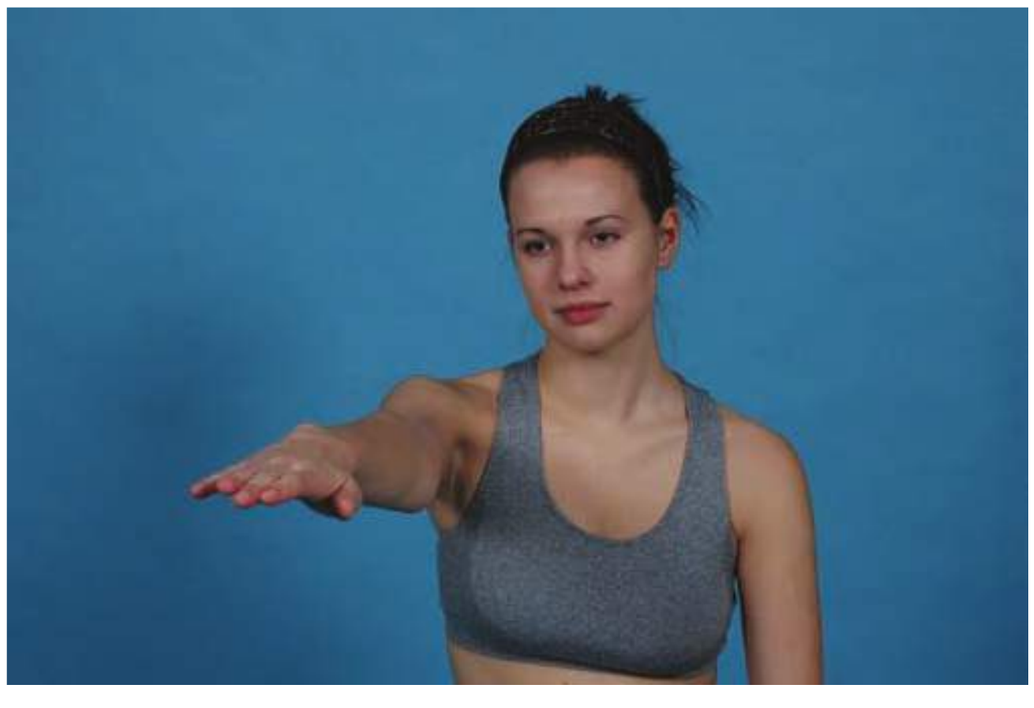

FIGURE 25-82 Front arm raise.

Closed kinetic chain activities can also be very helpful in rehabilitating weak shoulder girdle muscles and the cervical stabilizers (see Chapter 16).

It should be emphasized that all exercises should be performed correctly and without pain, although some degree of postexercise soreness can be expected. Isokinetic exercises of the neck are not functional and are not recommended as a strengthening tool.

Strength training can progress to manually resisted cervical stabilization exercises in various planes. Cervical proprioceptive neuromuscular facilitation patterns are ideal for this purpose (Chapter 10). Muscle cocontraction of agonist and antagonist can be used for joint stabilization, by increasing joint stiffness and supporting the independent torque-producing role of the muscles that surround the joint.[235–237]

Continued efforts must be made to progressively reduce the patient's pain and advance physical function through exercise.[136] However, the use of pain medication to help control pain and inflammation probably helps patients to progress, while experiencing considerably less pain and enabling their return to work.

Ergonomics

T e patient's workstation and lifestyle ergonomics should be addressed (Table 25-18). A chair that provides adequate support and encourages the patient to maintain lumbar lordosis provides a stable platform for the cervical spine.[238] T e feet should easily touch the floor, and the thighs should be horizontal to the ground. Computer monitors should be positioned to allow a slight 20-degree downward slope of the eyes.

Postural Retraining

It is important to retrain the patient to assume a correct upright and neutral spine position and to be able to consciously activate and hold the supporting muscles in a variety of functional positions.[69] Few studies have investigated the association between posture and active range of motion. Hanten et al.[239] measured resting head posture and total range between full protraction and retraction in the horizontal plane, in subjects with and without neck pain, and found that the neck pain group had less range than the normal group. Lee et al.[240] investigated associations between subclinical neck pain/discomfort, and range of motion and physical dimensions of the cervicothoracic spine. T eir data suggested that there are early range changes associated with the development of neck pain.

T e retraining of the cervicothoracic postural muscles usually begins at the lumbopelvic region, ensuring that the patient does not adopt the chest-out, shoulders-back position, which results in an incorrect thoracolumbar or thoracic lordosis, rather than a correct balance between all of the spinal curves.[69]

Overall Strength and Fitness

Strengthening of the entire kinetic chain should always be a consideration but will depend on the physical requirements of the patient. Strengthening exercises for the kinetic chain can include lat pull-downs VIDEO, PREs for the middle trapezius and rhomboids VIDEO, and upper extremity PNF patterns

TABLE 25-18 Workstation Setup and Keyboard Technique Checklist

Fault	Correction
Visual field	
Monitor positioned to side of keyboard	Monitor directly in front of chair and parallel to keyboard
Stationary monitor	Monitor mounted on adjustable support
Screen too high or too low	10–15-degree downward viewing angle to center of screen
Copy on desk surface	Copy secured alongside of monitor
Glare from direct and reflected light	Clean antiglare screen (glare filter and angle screen away from window)
Overhead fluorescent lights	Task-appropriate lighting
Incorrect focal distance for visual acuity	Focal distance (eyeglasses) corrected for computer use (i.e., 20–24 in)
Posture	
Head forward	Ears aligned with shoulders; chin retracted
Shoulders elevated	Shoulder girdle muscle balance
Scapular winging	Scapulothoracic proximal stability
Hypertonic upper trapezii	Lower keyboard or desk height
Shoulder protraction/internal rotation	Neutral shoulder alignment
Elbow flexion >90 degrees	Keyboard parallel to or slightly below elbow level (i.e., 80–90 degrees of elbow flexion)
Elbow flexion <80 degrees	Keyboard moved closer to minimize reach
Wrist flexion or extension	Height of keyboard or chair adjusted to achieve wrist in position of function[a]
Elbows locked at sides	Arms stabilized from scapulothoracic region
Wrists against keyboard or desk edge	Hard keyboard or desk edge padded
Wrist extension	Keyboard positive incline eliminated; flat keyboard or negative incline
Wrist ulnar deviation	Reeducate neutral wrist positioning; split keyboard
Finger MCP joint hyperextension	Fingers in position of function
Flat of kyphotic back	Back supports in chair to match individual spinal contours
Stationary chair back and seat pan	Versatile chair allowing forward, upright, and reclined postures; seat pan inclined forward with "waterfall" edge
Hips lower than knees	Seat height raised; seat pan inclined to position hips slightly higher (5–10 degrees) than knees
Feet dangling	Feet flat on floor or foot rest
Keyboard technique	
Wrist extensor/flexor co-contraction	Light key touch; relaxation-biofeedback training
Wrist ulnar deviation	Wrist aligned with forearm
Intrinsic plus keystrike	Hand postures in position of function
Intrinsic minus keystrike (zig-zag)	
Digital extensor habitus	Thumb lightly resting on spacebar; spacebar use with thumb press versus lift and strike
Thumb held in horizontal abduction and extension	
Excessive force of keystrike	Keystrike with finger press versus lift and strike; keystrike with arm bounce
Ulnar deviation at wrist and fingers	Wrist aligned with forearm; use of external rotation–abduction at shoulder for lateral key reach with lateral keystrike
Excessive leaning on wrist rests	Wrist glide versus wrist rest technique
Fifth finger lateral reach and strike	Index finger use for lateral keystrike: slight supination with fifth finger keystrike
Hands play with combination keystrikes	Combination key command efficiency; macroprogram development
Typing too fast	Kinesthetic awareness training
Infrequent breaks and poor work–rest cycles	Periodic rest breaks and task rotation; computer programmed to signal rest breaks

MCP, metacarpophalangeal.

[a]Position of function: forearm, wrist, and hand aligned, 20–30-degree wrist extension, natural curve to digits with MCP joints at about 50 degrees of flexion, and thumb in line with radius.

Data from Rempel DM, Harrison RJ, Barnhart S. Work-related cumulative trauma disorders of the upper extremity. JAMA. 1992;267:838–842; Armstrong TJ. Ergonomics and cumulative trauma disorders. Hand Clin. 1986;2:553–565.

VIDEO. It is important throughout the rehabilitation process for patients to maintain their level of cardiovascular fitness as much as possible. Aerobic exercise, which increases endurance and the general sense of well-being, should be a part of all exercise programs.[241,242] Cardiovascular conditioning should be started as soon as possible to prevent deconditioning. T ese exercises also serve as a great warm-up before a stretching program.

PRACTICE PATTERN 4B: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH IMPAIRED POSTURE

Fiber composition studies have demonstrated that the primary dysfunction in neck muscles is a loss in the tonic supporting capacity, with the dysfunction being greater within the neck flexors.[69,243] Several postural syndromes of the cervical region have been identified over the years.

Upper (Proximal) Crossed Syndrome

T is syndrome involves adaptive shortening of the levator scapulae, upper trapezius, pectoralis major and minor, SCM, and weakness of the deep neck flexors and lower scapular stabilizers. T e syndrome is characterized by the following[84,85]:

- Elevation and protraction of the shoulder;
- Rotation and abduction of the scapula;
- Scapular winging;
- Forward head (see the discussion that follows);
- Decreased stability of the glenohumeral joint;
- Increased muscle activity of the levator scapula and trapezius.

T e positional changes that occur with the proximal crossed syndrome may alter the structural relationships of the shoulder and the cervical spine. T is alteration may result in changes in the length–tension relationships and the kinematics of the scapular and cervical muscles. T e consequences of these changes may include posterior nerve root irritation, cervical radiculopathy, segmental hypermobility, and instability at C4–5.[116,244]

T e intervention for this syndrome is based on the clinical findings. Any changes in the length–tension relationships should be addressed through stretching and strengthening.

Forward Head

Abnormal posture adaptations have long been considered by many to be the cause of numerous musculoskeletal and neurovascular impairments (see Chapter 6).[53,61,71,245–254] T ese adaptations are further perpetuated by the natural cycle of aging of the spine, which involves disk degeneration, vertebral wedging, ligamentous calcification, and reduction in the cervical and lumbar lordoses, producing a position of spinal flexion, or stooping.

Habitual movement patterns or positions may contribute to the development of these changes and produce muscular hyperactivity, ligamentous stress, and alteration of the anatomic and biomechanical relationship of the joints. It is theorized that if a muscle lengthens as part of this compensation, muscle spindle activity increases within that muscle, producing reciprocal inhibition of the muscle's functional antagonist, and resulting in an alteration in the normal force–couple and arthrokinematic relationship, thereby affecting the ef cient and ideal operation of the movement system.[125,127,255–257]

Because the zygapophyseal joints in the midcervical region incur more weight bearing, as a result of the protruding head, marginal osteophytosis may occur. T e common levels for this to occur are C5–6 and C6–7. T ese changes also alter the scapulothoracic rhythm because of alterations in the muscle tone of the rhomboids and serratus anterior. T ese altered relations increase the distance between the origin and insertion of the trapezius, of the rhomboid major and minor, and of the levator scapulae, which results in further stress.

T e intervention for postural dysfunction focuses on the correction of any strength and flexibility imbalances. Once the mechanical source is identified, the focus is the simultaneous retraining of the muscles, by contracting the lengthened muscle when it is in a shortened position, and stretching the shortened muscle.[127] An exercise program for forward head posture should address underlying sot tissue imbalances by including deep cervical flexor and shoulder retractor strengthening and cervical extensor and pectoral muscle stretching. T erapeutic exercise programs initially should focus on the achievement of good movement patterns. Pearson and Walmsley[258] found that repeated upper cervical retractions changed resting neck posture. Roddey et al.[259] demonstrated improvements in resting scapular position following a stretching program of the pectoralis minor muscle. Wright et al.,[260] in a randomized, controlled study of a postural correction program consisting of scapular strengthening and neck stretching exercises for clients with temporomandibular disorder and pain, reported a significant improvement in symptoms (jaw and neck pain) as compared to the control group.[261]

Recommended exercises include the following:

- T e head nod exercise progression.
- T e return to normal exercise progression.
- Resisted shoulder retraction exercises in standing using theraband. T is is progressed to shoulder retraction in prone using weights.
- Unilateral and bilateral pectoralis minor stretches.
- Exercises to reposition the head into a natural head posture, as appropriate, using a mirror. Once the patient is able to reposition the head with the eyes open, the task is repeated with the eyes closed and the clinician providing feedback.[262]
- Exercises to retrain the oculomotor system. T ese exercises are initiated by asking the patient to keep the head stationary in the natural head posture and using the eyes to track objects.[262] Once this is mastered, the patient is asked to combine eye movements and head movements. For example the patient is asked to rotate the head and eyes at the same time in the same direction, then to rotate

the head and eyes in the opposite direction at the same time. Obviously, these exercises should not be performed if symptoms such as dizziness and unsteadiness appear. A study by Humphreys and Irgen found that these exercises reduced pain intensity and improved the accuracy of repositioning of the head at er 4 weeks of treatment in patients with chronic neck pain, compared with patients who did not receive treatment. However, as the authors acknowledged, a link still has to be made to establish the connection between craniovertebral kinesthesia, head reposition accuracy, and neck pain.

PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Cervical Strain

Approximately 20% of the population experiences a cervical strain at some time in their life,[263] with the incidence increasing with age, becoming the most prevalent between the fourth and fit h decades of life.[264] Although the majority of neck pain is mechanical in nature, it can become so severe that it interferes with activities of daily living, or it can become a source of chronic pain in certain individuals. In addition, the cost associated with treating neck pain continues to rise exponentially.[265]

Cervical Disk Pathology

T e cervical spine is vulnerable to the same impairments as those of the lumbar spine and any weakness in the surrounding structures results in either a disk bulge or a rupture. Cervical radiculopathy is, by definition, a disorder of the cervical spinal nerve root and, most commonly, is caused by a cervical disk herniation or other space-occupying lesion, resulting in nerve root inflammation, impingement, or both. Considering the structure of the cervical AF, the possibilities that emerge from mechanisms of diskogenic pain are strain or tears of the anterior AF, particularly at er hyperextension trauma, and strain of the alar portions of the PLL when stretched by a bulging disk.[11]

Analysis of the anatomic proportions of the cervical spine indicates that cervical diskogenic disease can have an impact on neural structures in the bony spinal canal. T e anterior–posterior diameter of the cervical spinal canal tends to be narrower in patients with herniation resulting in myelopathy.[76,266,267] T at is, patients with wide canals might be non-myelopathic even with the same degree of herniation. In the lumbar disk, a prolapse is common. In the cervical spine, a straightforward prolapse is uncommon, and a cervical disk herniation should not be considered as a miniature version of lumbar disk herniation. It is, unlike lumbar disk herniation, extremely rare under the age of 30 years, with the age range of peak incidence between 45 and 54 years, and only slightly less common in the 35–44-year-old group.[268] Acute disk herniations may result in compression of nerve roots. Cervical disks may become painful as part of the degenerative cascade, from repetitive microtrauma, or from macrotrauma. T e indication that degeneration plays a greater role in cervical disk herniation may explain why cervical disk herniation is extremely rare in those less than 30 years of age and why the mean age is around 50 years.[269,270]

T e most common level of cervical nerve root involvement has been reported at the seventh (C7, 60%) and sixth (C6, 25%),[22,271] followed by C–5 disk.[269,270,272] In a study of 18 cadavers by Tanaka et al.,[19] the C5 nerve roots were found to exit over the middle aspect of the IVD, whereas the C6 and C7 nerve roots were found to traverse the proximal part of the disk. T e C8 nerve roots had little overlap with the C7–T1 disk in the intervertebral foramen. T e C6 and C7 rootlets passed two disk levels in the dural sac. Also, a high incidence of the intradural connections between the dorsal rootlets of C5, C6, and C7 segments was found.[19] T ese intradural connections between dorsal nerve roots and the relation between the course of the nerve root and the IVD may explain the clinical variation of symptoms resulting from nerve root compression in the cervical spine.[19]

Cervical IVDs with herniation usually remain normal in height or change only slightly without abnormality in the uncovertebral joints.[269] Sclerosis and formation of osteophytes in the uncovertebral joints accompany narrowed disks in spondylosis. T ese facts indicate that the uncovertebral joints bear a part of the axial load to the IVD in the cervical spine. Accordingly, disk degeneration may play a more important role than trauma in the production of herniation in the cervical spine, and it is common for a patient to awake with a cervical disk herniation, misinterpreting it as a "crick" in the neck.

CLINICAL PEARL

Asymptomatic cervical disk herniation is often found in magnetic resonance images for other diseases.[22] Boden et al[16] reported the incidence of cervical disk protrusions in the asymptomatic population to be 10–15%, depending on age.

Other factors associated with increased risk include heavy manual labor requiring lit ing of more than 25 lb, smoking, and driving or operating vibrating equipment.[273]

Cervical disk degeneration occurs in a predictable fashion. T e NP and AF form small cysts[274,275] and fissures as the first disruptive changes at er the death of chondrocytes and the separation of fibers or fiber bundles. Subsequently, they extend and unite to form horizontal and vertical clet s.[269] Shearing stress to the disk by translational motion may lead to fibrillation of the matrix, as in osteoarthritic joint cartilage. Some of the vertical clet s extend to the cartilaginous end plate, and portions of the cartilaginous end plate may be torn off.

T e cervical IVD is innervated by the sinuvertebral nerve, formed by branches from the anterior (ventral) nerve root and the sympathetic plexus.[276] Once formed, the nerve turns back into the intervertebral foramen along the posterior aspect of the disk, supplying portions of the AF, PLL, periosteum of the

vertebral body and pedicle, and adjacent epidural veins. As in the lumbar spine, the pain associated with cervical disk lesions probably occurs from an inflammatory process initiated by nerve root compression, resulting in nerve root swelling.

Within the compressed nerve root, intrinsic blood vessels show increased permeability, which secondarily results in edema of the nerve root.[277] Chronic edema and fibrosis within the nerve root can alter the response threshold and increase the sensitivity of the nerve root to pain.[278] Neurogenic chemical mediators of pain released from the cell bodies of the sensory neurons and nonneurogenic mediators released from disk tissue may play a role in initiating and perpetuating this inflammatory response.[279] The posterior (dorsal) root ganglion has been implicated in the pathogenesis of radicular pain. Prolonged discharges originate from the cell bodies of the posterior (dorsal) root ganglion as a result of brief pressure.[277] In addition to the chemicals produced by the cell bodies of the posterior (dorsal) root ganglion, the membrane surrounding the posterior (dorsal) root ganglion is more permeable than that around the nerve root, allowing a more florid local inflammatory response.[277] The blood supply to the nerve root is usually not compromised by an acute herniation, unless the compression is severe.[23,280] A study involving patients under local anesthesia found that compression of the cervical nerve root produced limb pain, whereas pressure on the disk produced pain in the neck and the medial border of the scapula.[13,281] Intradiskal injection and electrical stimulation of the disk have also suggested that neck pain is referred by a damaged outer AF.[281,282] Muscle spasms of the neck have also been found after electrical stimulation of the disk.

The capacity of the disk to self-repair is restricted by the fact that only the peripheral aspect of the AF receives blood and a small amount at that.

Numerous clinical examination findings are purported to be diagnostic of cervical radiculopathy including patient history, CROM limitations, neurologic examination, and specific maneuvers (e.g., Spurling). Most of these items have demonstrated a fair or better level of reliability.[152] However, because the clinical presentation of cervical radiculopathy is so variable, it is advisable to use a combination of test results before making a diagnosis.[152]

It is important to obtain a detailed history to establish a diagnosis of a cervical radiculopathy and to rule out other causes, such as TOS and brachial neuritis. The clinician should first determine the main complaint (i.e., head or neck pain, numbness, weakness, decreased neck function) and location of symptoms.[12,223] Anatomic pain drawings can be helpful by supplying the clinician with a quick review of the pain pattern.

CLINICAL PEARL

Patients with a cervical disk herniation are often younger, whereas patients with radicular symptoms due to cervical disk degeneration are often middle aged.

Henderson et al. reviewed the clinical presentations of cervical radiculopathy in 736 patients[283]: 99.4% had arm pain, 85.2% had sensory deficits, 79.7% had neck pain, 71.2% had reflex deficits, 68% had motor deficits, 52.5% had scapular pain, 17.8% had anterior chest pain, 9.7% had headaches, 5.9% had anterior chest and arm pain, and 1.3% had left-sided chest and arm pain (cervical angina). Neurologic deficits corresponded with the offending disk level in approximately 80% of patients.[277]

The patient usually reports a history of neck pain before the onset of arm pain. The onset of neck and arm discomfort with cervical disk herniation is usually insidious and can range from a dull ache to severe burning pain.[12,223] The symptoms may be referred to the medial scapula initially and then along the upper or lower arm and into the hand, depending on the nerve root that is involved.[12,223]

Patients with a cervical disk lesion typically have severe pain that prevents them from getting into a comfortable position.[277] The symptoms are usually aggravated by extension or rotation of the head to the side of the pain (the Spurling maneuver) (Fig. 25-56). Aggravation of the symptoms by neck extension often helps differentiate a radicular etiology from muscular neck pain or a pathologic condition of the shoulder with secondary muscle pain in the neck.[277]

The common radicular syndromes of the cervical spine are outlined in Table 25-19.

C2–3 disk herniations are rare,[284] in either traumatic or spontaneous etiology, and affected only 8 of 2786 patients (0.28%) of the surgical cervical spondylotic cases over 10 years in one study.[285] These herniations are difficult to identify on clinical examination because these patients usually have no specific motor weakness or reflex abnormality. Radiculopathy of the third cervical nerve root results from pathologic changes in the disk between the second and third cervical levels and is unusual. The posterior ramus of the third cervical nerve innervates the suboccipital region, and involvement of that nerve causes pain in this region, often extending to the back of the ear.

Radiculopathy of the fourth cervical nerve root may be an unexplained cause of neck and shoulder pain.[277] Numbness extending from the caudad aspect of the neck to the superior aspect of the shoulder may be present. Difficulty with breathing during physical exercise may be reported in diaphragmatic involvement (C3–5).

Radiculopathy of the fifth cervical nerve root can present with numbness in an "epaulet" distribution, beginning at the superior aspect of the shoulder and extending laterally to the midpart of the arm.[277] The absence of pain with a range of motion of the shoulder and the absence of impingement signs at the shoulder help to differentiate radiculopathy of the fifth cervical nerve root from a pathologic shoulder condition.[277]

Radiculopathy of the sixth cervical nerve root presents with pain radiating from the neck to the lateral aspect of the biceps, down the lateral aspect of the forearm, to the posterior (dorsal) aspect of the web space between the thumb and the index finger, and into the tips of those digits.[277] Numbness occurs in the same distribution.

The seventh cervical nerve root is considered to be the most frequently involved by cervical radiculopathy. The patient has pain radiating to the back of the shoulder, often extending into the scapular region, down along the triceps, and then along the posterior aspect of the forearm and into the posterior aspect of the long finger.[277] The patient usually pronates the forearm while trying to describe the location of the symptoms, and this is a useful observation in differentiating the hand symptoms

TABLE 25-19 Common Radicular Syndromes of the Cervical Spine

Disk Level	Nerve Root	Motor Deficit	Sensory Deficit	Reflex Compromise
C4–5	C5	Deltoid Biceps	Anterolateral shoulder and arm	Biceps
C5–6	C6	Wrist extensors Biceps	Lateral forearm and hand Thumb	Brachoradialis Pronator teres
C6–7	C7	Wrist flexors Triceps Finger extensors	Middle finger	Triceps
C7–T1	C8	Finger flexors Hand intrinsics	Medial forearm and hand and ring and little fingers	None
T1–2	T1	Hand intrinsics	Medial forearm	None

Data from American Medical Association. Guides to the Evaluation of Permanent Impairment. 5th ed. Chicago, IL: American Medical Association; 2001.

from those of sixth cervical radiculopathy and carpal tunnel syndrome.[277]

Radiculopathy of the eighth cervical nerve root usually presents with symptoms extending down the medial aspect of the arm and forearm and into the medial border of the hand and the ulnar two digits.[277] Numbness usually involves the posterior and anterior aspects of the ulnar two digits and hand and may extend up the medial aspect of the forearm. The patient reports difficulty with using the hands for routine daily activities.[277]

Patients can also present with radicular symptoms that result from other pathologies. These can include schwannomas, meningiomas, and benign or malignant vertebral body tumors.[277] A Pancoast tumor of the apical lung can involve the more inferior cervical nerve roots and, additionally, the sympathetic chain.[277] Idiopathic brachial plexus neuritis is thought to be viral in nature and presents with severe arm pain that resolves and leaves behind polyradicular motor deficits. Polyradicular involvement may also be seen with epidural abscesses.[277]

In middle-aged and older patients, the symptoms are often the result of degenerative changes and compression of the neural structures by osteophytes rather than disk herniation. Prior episodes of similar symptoms or localized neck pain are important for the diagnosis and ultimate intervention. The older patient may have had previous episodes of neck pain or give a history of having arthritis of the cervical spine. Leg symptoms associated with neck dysfunction, especially in the elderly, should arouse the suspicion of cervical spondylotic myelopathy.[267]

The position of the head and neck at the time of injury should also be noted. Acute disk herniations and sudden narrowing of the neural foramen may occur from injuries involving cervical extension, side bending, or rotation and axial loading.[286,287]

The clinician should be aware that upper trunk brachial plexus disorders can be confused with a C5 or C6 radiculopathy. This condition often referred to as a burner, or stinger, is thought to result from either traction or compressive forces to the brachial plexus or cervical nerve roots.[288,289] At times, electrodiagnostic studies and magnetic resonance imaging (MRI) are needed to establish the diagnosis.

Peripheral nerve entrapment within the upper limb, including entrapment or compression of the suprascapular, median, and ulnar nerves, may also be confused with a cervical radiculopathy[12,223]:

- A suprascapular neuropathy can be confused with a C5 or C6 radiculopathy but would spare the deltoid and biceps muscles.
- C6 and C7 radiculopathies are most likely to be confused with median neuropathies.
- A C8 radiculopathy must be differentiated from ulnar neuropathies and TOS.

It is important to differentiate an eighth cervical radiculopathy from ulnar nerve weakness. The function of the flexor digitorum profundus in the index and long fingers and of the flexor pollicis longus in the thumb can be affected by an eighth cervical radiculopathy, but they are not affected by ulnar nerve entrapment.[277] With the exception of the adductor pollicis, the short thenar muscles are spared with ulnar nerve involvement but are involved with an eighth cervical or first thoracic radiculopathy.[277] Entrapment of the anterior interosseous nerve may masquerade as an eighth cervical or first thoracic radiculopathy, but it does not cause the sensory changes or have thenar muscle involvement.[277]

The head and neck positions or motions that increase or decrease the symptoms can be used by the clinician both to help in the diagnosis and to plan the intervention. Typically, the patient with cervical radiculopathy has a head list away from the side of injury and holds the neck stiffly. These patients complain of increased posterior neck pain with neck positions that cause foraminal narrowing: extension, side bending, or rotation toward the symptomatic side.

Active range of motion is usually reduced in the direction of pain, which is usually extension, rotation, and side bending, either toward or away from the affected nerve root. Side bending away from the affected side can cause increased displacement of a disk herniation on a nerve root whereas same-side bending induces pain by an impingement of a nerve root at the site of the neural foramen.[286,287]

Anterior neck pain along the SCM muscle belly, which is aggravated by rotation to the contralateral side, is most ot en a result of muscular strain.[277] Pain in the posterior neck muscles, which is worsened by flexion of the head, suggests a myofascial etiology.[277] Patients who present with severe pain in the suboccipital region ot en have pathologic changes in the upper cervical spine.[277] T e pain in these patients may radiate to the back of the ear or the lower neck. Rotation of the neck is ot en markedly restricted.

On palpation, a nonspecific finding is a tenderness noted along the cervical paraspinals, along the ipsilateral side of the affected nerve root, and over the upper trapezius. T ere may also be muscle tenderness along muscles where the symptoms are referred (e.g., medical scapula, proximal arm, and lateral epicondyle), as well as associated hypertonicity or spasm in these painful muscles.

Manual muscle testing determines a nerve root level on physical examination and can detect subtle weakness in a myotomal, or key muscle, distribution. Weakness of shoulder abduction suggests C5 pathology, elbow flexion and wrist extension weakness suggests a C6 radiculopathy, weakness of elbow extension and wrist flexion can occur with a C7 radiculopathy, and weakness of thumb extension and ulnar deviation of the wrist is seen in C8 radiculopathies.[281]

On sensory examination, a dermatomal pattern of diminished, or loss of, sensation should be present. In addition, patients with radiculitis may have hyperesthesia to light touch and pinprick examination.[281] T e sensory examination can be quite subjective, however, in as much as it requires a patient response.

Muscle stretch reflexes are helpful (see Table 25-19). Any grade of reflex can be normal,[290] so the asymmetry of the reflexes is most helpful:

- T e biceps brachii reflex occurs at the level of C5–6. T e brachioradialis is another C5–6 reflex.
- T e triceps reflex tests the C7–8 nerve roots.
- T e pronator reflex can be helpful in differentiating C6 and C7 nerve root problems. If it is abnormal in conjunction with an abnormal triceps reflex, then the level of involvement is more likely to be C7. T is reflex is performed by tapping the anterior aspect of the forearm, with the forearm in a neutral position and the elbow flexed.[290,291]

Little is known about the natural history of cervical radiculopathy, and there are few randomized controlled studies comparing operative with conservative intervention, although the outcome data support the concept that an extruded disk actually may have a more favorable prognosis than contained disk pathology.[222,292]

Conservative intervention consists of modified rest, a cervical collar, oral corticosteroid "dose-packs," and NSAIDs.[293,294] Oral corticosteroids have been used to reduce the associated inflammation from compression, although there is no controlled study to support their use in the intervention of cervical radiculopathy.[222,286] T e beneficial effect of corticosteroids may occur as a result of the anti-inflammatory properties of these drugs. Cervical epidural corticosteroids have also been used in patients who have not responded to medications, traction, and a well-designed physical therapy program.

Exercise programs for patients with disk herniations are individualized.[223] Cervical and cervicothoracic stabilization exercises form the basis of the therapeutic exercise progression. Most patients obtain analgesia using the controlled use of cervical retraction or posterior gliding of the lower cervical spine, in combination with extension of the lower cervical spine and flexion of the upper cervical spine (chin tuck),[295] although repetitive use of this exercise has the potential to cause harm and should be used only as long as the patient is achieving benefit.

T e majority of studies investigating the outcomes of patients with cervical radiculopathy have used generic self-report measures or measures of pain. Two condition-specific measures that have been shown to be reliable and valid in patients with cervical radiculopathy are the NDI (Chapter 5) and the patient specific functional scale.[296]

Surgical Intervention

Surgical intervention is reserved for patients with persistent radicular pain who do not respond to conservative measures (see later discussion).[297] In general, the decision to proceed with surgical intervention is made when a patient has significant extremity or myotomal weakness, progressive neurologic deficits, severe, unremitting pain, or pain that persists beyond an arbitrary "conservative" intervention period of 8–12 weeks.[298] Based on this criteria, surgical treatment for cervical disk herniation is needed in only a very small percentage of individuals. Compressive pathologic lesions causing cervical radiculopathy (sot disk fragment herniation or spondylotic bone spurs) are most ot en located anterior to the nerve root.[299] Typically, lateral cervical disks are removed by the posterior approach, whereas the anterior approach is used with prolapsed midline disks that compromise the spinal cord, or some paramedian disks that compromise either the spinal cord or the nerve root but do not extend beyond the lateral margin of the cervical cord.[300]

T e common surgical procedures for cervical disk injuries include (1) anterior cervical discectomy and fusion, (2) laminectomy and laminotomy–facetectomy, (3) laminectomy or laminoplasty (with or without fusion), and (4) anterior corpectomy and fusion.

Anterior Cervical Discectomy and Fusion. A herniated disk in the neck is commonly approached anteriorly. Both lateral and central disks can be removed through this anterior approach. T e results from cervical diskectomy have shown an approximately 95% chance of good-to-excellent relief from the radiating arm pain.[294] Numbness in the upper extremity generally improves. Typically, the patient may resume full, unrestricted activities within 3–6 months following surgery. Complications from this surgery are very rare, with the most common being a transient sore throat, hoarseness, dif culty swallowing, failure of bony fusion, and pseudoarthrosis. Although fusions provide inherent stability to the motion segment and immobilize potentially painful degenerative disk and facet joints, the disadvantages, especially in a highly mobile cervical spine segment, include the increased possibility of further progression of degenerative changes at other disk levels, which eventually requires further surgery.[301]

Anterior Corpectomy and Fusion. T e anterior approach for this technique is the same as for the anterior cervical discectomy and fusion. T e appropriate disks are incised and removed back from the PLL. T e cervical spine is stabilized at er corpectomy with strut bone grat s. Internal fixation is ot en indicated to provide additional rigidity. Postoperatively a rigid cervical orthosis is typically used.

Laminectomy. T is procedure, typically indicated for spinal stenosis, is designed to resect the lamina on one or both sides, to increase the axial space available for the spinal cord. T e indication in the context of cervical disk disease is when more than three levels of disk degeneration with anterior spinal cord compression are present. Single-level cervical disk herniation is ideally managed from the anterior approach. T e complications of the posterior approach include instability leading to kyphosis, recalcitrant myofascial pain, and occipital headaches. Post-laminectomy kyphosis requires revision surgery. If preexistent kyphosis is present, an anterior approach is favorable because in a patient with kyphosis, laminectomy may accelerate kyphosis. As an alternative to laminectomy, a foraminotomy can be used to remove a single-level unilateral lateral disk herniation. T is involves removal of 50% of the zygapophyseal joint on one side. T is procedure is effective when radicular arm pain is greater than axial neck pain. Foraminotomy can also be performed anteriorly and has a success rate of 91% in relieving radicular pain.[301]

Laminaplasty. Laminaplasty is commonly indicated for multilevel spondylotic myelopathy. Comparative studies with laminectomy have shown that patients with laminaplasty have superior functional recovery in spondylotic myelopathy.[302–305] T e incidence of spinal cord injury with laminaplasty is approximately 10 times lower than that of laminectomy.[302–305] Nerve root injury is commonly seen in about 11% of the surgeries.[302–305] T is complication is unique to laminaplasty, and the suggested etiology is traction on the nerve root with posterior migration of the spinal cord.[302–305]

In the best case scenario, the surgeon chooses the technique that directly eliminates the nerve-compressing lesion, while preserving the motion segment of the spine. T e anterior microforaminotomy procedure has shown promising results in preserving the remaining disk and the intervertebral space as much as possible while directly eliminating the compressive pathologic lesion.[306,307] T e advantages of this technique are many, including removal of only the offending mass, preservation of most of the disk and motion segment, a shorter operative procedure and hospital stay, avoidance of a fusion procedure and the attendant potential problems, and an earlier return to full activity. T e disadvantages are the long-term issues related to disk degeneration and unilateral removal of an uncovertebral joint.[301]

Patients who undergo spinal surgery may receive physical therapy as part of their rehabilitation. Although there is a large amount of information from evidence-based clinical practice guidelines for the management of many musculoskeletal conditions, there is relatively little information available on the physical therapy management of patients who have undergone spinal surgery.

T e RCTs comparing various physical activity programs[308–311] have demonstrated the benefits of these programs. T ese benefits have included less pain and disability, improved range of motion, and greater satisfaction with care.

Before the surgery, the patients may receive advice on spine care, postsurgical precautions, and instructions on basic exercises.

T e postsurgical intervention following surgery is as varied as the number of types of surgery. T e following are guidelines for postsurgical rehabilitation. T e primary goals for the initial period following the surgery are as follows:

- Reduction of pain and inflammation;
- Prevention of postsurgical complications;
- Protection of the surgical site;
- Prevention of recurrent herniation;
- Maintenance of dural mobility;
- Improvement of function;
- Minimizing of the detrimental effects of immobilization.[312–317];
- Early return to appropriate, functional activities; patients are usually permitted to shower 1 week at er the surgery;
- Safe return to occupational duties; patients with a sedentary occupation may return to work within 7–10 days at er the surgery; prolonged positions and postures are to be avoided; and
- Patient education on correct body mechanics and independent self-care.

T e patient is given guidance on the gradual resumption of daily activities. Immobilization or prolonged rest should be avoided. Instead, the patient is encouraged to walk for short periods and distances several times a day.

Outpatient physical therapy, if appropriate, usually begins in the second or third week. T e physical therapy examination includes the following:

- A thorough history;
- Inspection of the wound site;
- Anthropometric data;
- Postural examination; and
- Neural examination, including neurodynamic mobility, and strength testing.

T e components of the physical therapy intervention include a graded exercise program, with gentle range of motion, submaximal isometrics, and arm and leg exercises as appropriate.

Additional interventions may include electrotherapeutic modalities, physical agents, and scar massage. Patient education is very important, particularly postural education and information on body mechanics.

Progressive strengthening exercises for the spinal stabilizers are usually initiated by the fourth postoperative week.

Cardiovascular conditioning exercises are introduced at the earliest opportunity based on patient tolerance. T ese include riding a stationary bicycle, using an upper body ergometer and a stair-stepper, and swimming in a pool. T e sessions for these exercises are initially brief (5–10 minutes) and are gradually increased up to 30–60 minutes.

Activities such as jogging are usually permitted at 6–8 weeks if there is minimal pain. When the patient does resume

these activities, they should be done in the morning hours when the IVD is maximally hydrated.[318] High-impact sports such as basketball and soccer are usually permitted at er the 12th week.

Cervical Spondylosis

Cervical spondylosis is a chronic degenerative condition affecting the contents of the spinal canal (nerve roots and/or spinal cord) and the cervical vertebral bodies and IVDs, and is the most common cause of progressive spinal cord and nerve root compression. T e characteristics of degenerative joint disease (DJD) and DDD relate to bony changes, and the two ot en occur concurrently.[10] Abnormalities in the osseous and the fibroelastic boundaries of the bony cervical spinal canal or in the lateral recess and foramina affect the availability of space for spinal cord and nerve roots, resulting in a myelopathy or stenosis, respectively. Cyriax[162] reserved the term spondylosis for the end stage of spinal diseases, although the term is now used to describe varying levels of degenerative changes in the cervical spine.[10] Although this condition ot en remains asymptomatic for a long time, it can become a major influence in the production of radiculomyelopathic compressive disturbances, when other conditions, such as spondylosis, diskal hernia, and trauma become superimposed. As the resulting space for neural structures becomes smaller, the risk of developing motor and/or sensory disturbances increases.

Progressive degenerative changes are expected to appear over time on radiographs as part of the natural history of the aging spine. Radiographic evidence of cervical degeneration is observed in some 30-year olds and is present in more than 90% of people older than 60 years of age.[319] T e areas most commonly and most severely affected are C5–6 and C6–7.[36] Although aging of the cervical spine is ubiquitous, controversy remains about whether the process of spondylosis may be accelerated in patients with a history of sot tissue injuries to the neck and persistent pain. However, in the absence of pain, the finding of degenerative changes on radiographs should not be misconstrued as pathologic. One study reported evidence of cervical spondylosis in 35% of asymptomatic individuals.[320]

Kirkaldy-Willis[321] categorized spondylosis of the spine into three stages:

- Dysfunctional. During this stage, the patient complains of a gradual onset of neck or arm symptoms (radiculopathy), or both, that have increased frequency and severity.[10]
- Unstable. During this stage, the pain is ot en worse when the patient is in certain positions, and can interfere with sleep. Morning stiffness of the neck, which gradually improves throughout the day, is a common finding.
- Stabilization. During this stage, lateral nerve root entrapment becomes more common. In some cases, the spinal cord or anterior spinal vessels may be compressed resulting in cervical myelopathy and/or vertebrobasilar insuf ciency.[322] T e blood supply of the spinal cord is an important anatomic factor in the pathophysiology. Radicular arteries in the dural sleeves tolerate compression and repetitive minor trauma poorly. T e spinal cord and canal size are also factors.

CLINICAL PEARL

Osteoarthritis in the cervical spine is, in effect, the later stages of spondylosis, and is marked by progressive degeneration of the IVD and, especially, the zygapophyseal joint. Osteoarthritic changes can include osteophyte formation, hypertrophy of the synovial membrane and, in some cases, a chronic inflammatory response.

T e physical examination findings depend on the degree of severity but can include reduced motion in the sagittal plane, with a decrease in side bending in the early stages. As the degeneration progresses, a capsular pattern develops.[162] Cervical spondylotic myelopathy is the most serious consequence of cervical IVD degeneration, especially when it is associated with a narrow cervical vertebral canal. Five categories of cervical spondylotic myelopathy are described in Table 25-20, based on the predominant neurologic findings. Myelography, with CT, is usually the imaging test of choice to assess spinal and foraminal stenosis.

T e conservative intervention for cervical spondylosis without radiculopathy or myelopathy involves the use of electrotherapeutic modalities to control pain and increase the extensibility of the connective tissue. T ese modalities usually include moist heat, electrical stimulation, and ultrasound. Immobilization of the cervical spine may be considered for

TABLE 25-20 Characteristics of the Different Syndromes of Cervical Spondylotic Myelopathy

Syndrome	Pain	Gait Abnormality	Involvement of the Extremities	Laterality
Lateral (radicular)	Yes	Sometimes	Upper	Often unilateral
Medial (myelopathic)	No	Yes	Lower	Usually bilateral
Combined	Sometimes	Yes	Upper and lower	Unilateral in upper extremities and bilateral in lower extremities
Vascular	No	Yes	Upper and lower	Bilateral
Anterior (painless weakness of the upper extremity)	No	No	Upper	Often unilateral

Data from Spivak JM, DiCesare PE, Feldman DS. Orthopaedics: A Study Guide. New York, NY: McGraw-Hill, 1999:349.

patients with nerve irritation to limit the motion of the neck and further irritation. In such instances, sot cervical collars are recommended initially. More rigid orthoses (e.g., Philadelphia collar and Minerva body jacket) can significantly immobilize the cervical spine. With the use of any of the braces, the patient's tolerance and compliance are under consideration. T e use of the brace should be discontinued as soon as feasible. Molded cervical pillows can better align the spine during sleep and provide symptomatic relief for some patients. Manual techniques may be used to stretch the adaptively shortened tissues. Range-of-motion exercises are performed as tolerated. T ese exercises are initially performed in the pain-free direction and then in the direction of pain. As the patient regains motion, isometric exercises and cervical stabilization exercises are prescribed.

Zygapophyseal Joint Dysfunction

T e patient with a zygapophyseal joint dysfunction typically reports an onset of unilateral neck pain, or "neck locking," following sudden backward bending, side bending, or rotation of the neck, or pain that followed a sustained head position. T e condition is thought to result from entrapment of a small piece of synovial membrane by the zygapophyseal joint.[98,114,323]

Palpation just lateral to the midline ot en indicates regional sot tissue changes in response to the underlying zygapophyseal joint injury, and combined motion testing usually shows a closing pattern of restriction corresponding to the injured zygapophyseal joint.[97]

Because traditional images (plain radiographs, computed tomography, and MRI) are typically unremarkable in the presence of zygapophyseal joint pain,[323] clinical suspicions of these joint injuries can be confirmed if necessary by diagnostic intra-articular zygapophyseal joint injections, or a block of the joint's nerve supply.[324,325]

T e conservative intervention involves the use of cryotherapy and electrotherapeutic modalities to control pain and inflammation. Joint mobilization techniques, involving combinations of flexion or extension and rotation, with traction superimposed, are applied initially in the pain-free direction and then in the direction of pain.

As the patient regains motion, range-of-motion and isometric exercises are prescribed until the full range of motion is restored, at which time the strengthening exercises are progressed.

An interesting study by Cleland et al.[326] investigated the predictive validity (clinical prediction rule [CPR]) of variables from the initial examination to identify patients with neck pain who are likely to benefit from thoracic spine thrust manipulation. T e study identified a CPR with six variables as follows:

1. Symptoms of less than 30 days;
2. No symptoms distal to the shoulder;
3. Looking up does not aggravate symptoms;
4. Fear-avoidance beliefs questionnaire (FABQ) (see Chapter 4) physical activity score less than 12;
5. Diminished upper thoracic spine kyphosis; and
6. Cervical extension range of motion less than 30 degrees.

T e study found that if three of these (positive likelihood ratio = 5.5) were present, the chance of experiencing a successful outcome from a thoracic spine thrust manipulation improved from 54% to 86%.

Acute Torticollis (Acute Wry Neck)

Torticollis is both a symptom and a disease. An acute form of torticollis, known as acute wryneck, typically develops overnight in young and middle-aged adults. T e precise etiology is unclear, but as most patients appear to experience symptoms shortly at er awakening, it may be the result of an injury to the muscles, joints, or ligaments through sleeping with the neck in an unusual position. T is unusual position may place the involved joints in a position of extreme motion, stretching the structures and increasing the risk of impingement when the joint position is returned to normal.

T e most common clinical presentation includes a painful neck, which is both visible and palpable. T ere is a marked limitation in range of motion of the neck, and the patient may hold the head in a position of comfort toward the side of the involved muscle. A common feature is the presence of limited to no radiographic correlation between the degree of pain presented by the patient in the neck and the degree of radiographic changes.

T e hanging head method is a simple but successful method for treating acute painful wry neck of spontaneous onset.[327] T e technique requires a table with the capacity to tilt the head down. T e patient is positioned in supine at the end of the table, and head down tilt of about 20 degrees is provided. T is position, which is maintained for 5–10 minutes, provides a gentle traction force allowing the SCM to relax. Alternatively, gentle traction can be applied manually. If this treatment is successful, no further intervention is necessary. In the cases where this technique is unsuccessful, the patient is reassured that they have a self-limiting condition and that the symptoms will usually resolve significantly within 7 days, with complete resolution within 2 weeks.[328]

Cervical Spine Instability

Punjabi defined clinical stability as "the ability of the spine, under physiological load, to limit patterns of displacement so as not to damage or irritate the spinal cord or nerve roots, and, in addition, to prevent incapacitating deformity or pain due to structural changes."[329] Cervical instability can occur secondary to trauma, surgery, systemic disease, or degenerative changes to the motion segment. Signs and symptoms associated with minor cervical instability include the following:[106]

- History of major trauma;
- Reports of catching/locking/giving way;
- T e unpredictability of symptoms;
- Subjective reports of neck weakness (head feels heavy);
- An altered range of motion;
- Neck pain with or without muscle spasms; and
- Reports of headaches.

To date, there is no gold standard for diagnosing minor instability in the midcervical spine, only a high degree of

suspicion based on signs and symptoms. In these cases, a cervicothoracic stabilization program is recommended to restore lost functional capacities, range of motion, muscular strength, and endurance.

PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Whiplash-Associated Disorders

T e term whiplash injury was introduced in 1928 by the American orthopaedist H. E. Crowe,[330] and it was defined as the effects of sudden acceleration–deceleration forces on the neck and upper trunk as a result of external forces exerting a "lash-like effect." Crowe emphasized that the term whiplash "describes only the manner in which a head was moved suddenly to produce a sprain in the neck."

Over recent years, the role of the physical therapist in the intervention of the consequences of whiplash-associated disorder (WAD) has increased dramatically. It is thus imperative that the clinician have a strong understanding of the mechanisms that produce the myriad of symptoms associated with this disorder.

Despite a great deal of attention, WADs remain an enigma as the subjective nature and high prevalence of the symptoms, in the absence of focal physical findings and positive imaging studies. Up to 50% of those who sustain a WAD from a motor vehicle collision (MVC) transition from acute to chronic pain,[331] which results in a substantial personal and economic burden.[332,333]

Def nition

T ere is little agreement as to the definition of WAD. Nordhoff[334] describes the whiplash injury as an injury that occurs because of occupant motions within a vehicle that is rapidly decelerating or accelerating, without reference to the body parts involved. Even the definition provided by the Quebec Task Force on WADs,[335] which, for whatever reason, did not include front-end collisions, offered the following vague definition:

Whiplash is an acceleration–deceleration mechanism *of* energy trans*fer* to the neck. It may result *f*rom rear-end or side-impact motor vehicle collisions, but can also occur through diving and other mishaps. T e impact may result in bony or so*ft* tissue injuries (whiplash injury), which in turn may lead to a variety *of* clinical mani*f*estations.

Mechanism

A number of mechanisms have been proposed that result in a WAD. T ese include the following:

- Motor vehicle accidents (MVCs);
- Sporting injuries involving a blow to the head or neck, or a heavy landing;
- Pulls and thrusts on the arms; and
- Falls, landing on the trunk or shoulder.

Perhaps the most common mechanism of WAD is the MVC. T e extent of injury from a WAD following an MVC depends, in part, on three factors: (1) the position of the head at the point of impact, (2) the amount of force involved, and (3) the direction of those forces.

Head Position. Pure extension injuries seem to be uncommon in a WAD because most injuries involve forced combinations of motion. T ese include a flexion or extension force applied to a rotated head and neck, resulting from a turned position on impact.[336] As many as 57% of persons sustaining whiplash injury, with symptoms persisting 2 years at er collisions, reported having their heads rotated out of the anatomic position at the time of impact.[337,338] In fact, the head position has been reported as the only accident feature of a collision event that has a statistically significant correlation with symptom duration.[338]

The Amount of Force. T e amount of force applied to the neck is approximately equal to the weight of the head and the speed with which the head moves. Consequently, the heavier the head or the faster it moves, the greater the stress that is put through the neck. However, it is well recognized by clinicians with any experience with post-MVC patients that some patients who have survived high-velocity accidents do better than many who appear to have been involved in trivial impacts.

Force Direction. Force direction plays a significant role in the degree of damage sustained by the patient. T e direction of the applied forces depends on the following[95]:

1. Where the car is hit, that is, front end, rear end, or side;
2. Symmetry of the impact, that is, directly head on or rear end, or the forward or backward side;
3. Whether the car is pushed ahead into another vehicle, the curb, or another stationary object; and
4. T e position of the victim in relation to the impact.

During the early phase of a rear-end collision, the occupant's trunk is forced upward toward the head, and the cervical spine undergoes a sigmoid deformation, resulting in the head being moved upward and backward.[339] During this motion, at about 100 milliseconds at er impact, the lower cervical vertebrae undergo extension, but without translation.[339] T is motion causes the vertebral bodies to separate anteriorly and the zygapophyseal joints to impact posteriorly.[339] T ese forces may lead to posterior dislocations.[340–342]

T e reason for the greater severity of hyperextension injuries over the other force directions is believed to be related to several factors, including[334]

- whether the seat back breaks;
- whether the occupant hits the front of the occupant space;
- the differential motion between the seat back and occupant;
- hyperextension of the neck over the head restraint; and
- rebound neck flexion as the head rebounds off the head rest.

Hyperflexion injuries are typically less severe because the amount of head excursion is limited by the chin striking the chest. T e damage incurred by cervical side-bending traumas depends on whether the head hits an object or the shoulder.[95]

A number of other variables also determine the type and extent of the injury[334]:

- Seat position
- Occupant size, height, and posture
- Vehicle interior design
- T e size of the vehicle
- Sex *of* driver. Women generally position their seats more forward than men, which places their bodies closer to the front car structures and, therefore, at higher risk of impacting the front interior
- Seat belt. T e subject of seat belts is controversial because the seatbelt appears to be responsible for more injuries than any other contact source in the car, albeit minor ones.[343] T is is, in part, because of their design, which restrains only one shoulder, and because the belt acts as a fulcrum for energy concentration on the occupant.[334] As of 1997, federal law has required all passenger vehicles to have air bags. Mortality reductions in frontal collisions associated with airbags have been estimated to be no greater than 25–30%[344] and perhaps substantially less[345] when compared with the approximately 50% reduction associated with proper use of seat belts.[346] Because airbags provide supplemental protection for occupants wearing a seat belt, it is necessary to compare the combined effect of airbags and seat belts either relative to device alone or completely unrestrained in order to adequately evaluate their effectiveness. A study by McGwin et al.[347] conducted a retrospective cohort study of front seat occupants involved in police-reported, tow-away, frontal motor vehicle collisions, using data from the 1995 to 2000 National Automotive Sampling System. Compared with completely unrestrained occupants, those using a seat belt alone or in combination with an airbag had a reduced overall risk of injury (relative risks, 0.42 and 0.71, respectively); no association was observed for those restrained with an airbag only (relative risk, 0.98). T e study concluded that airbag deployment does not appear to reduce significantly the risk of injury either alone or in combination with seat belts.[347] Population-based studies of airbag effectiveness against less serious injuries, which have been rare, seem to suggest that airbags may merely be altering the distribution of injuries.[334,348]
- Headrest height. Headrest height appears to play a role, with the driver ot en setting the head rest too low, or sitting too far forward to obtain adequate support from the head rest.[349,350] However, the fatal accidents involving hyperextension appear to occur in the absence of a head restraint, where there is no structural limitation to the head movement except anatomic structures.

Clinical Findings

It should be obvious that a meticulous examination of the traumatized patient is of paramount importance.[351] T e variability of signs and reported symptoms can challenge even the most experienced clinician. Signs and symptoms to alert the clinician include the following:

- UMN signs and symptoms;
- Periodic loss of consciousness;
- Loss of concentration and short-term memory;
- Dif culty swallowing;
- T at the patient does not move the neck, even slightly (fractured dens);
- Painful weakness of the neck muscles (fracture);
- Gentle traction and compression of the neck that are painful (fracture);
- Severe muscle spasm (fracture);
- Complaints of dizziness;
- Insomnia; and
- Depression.

T e symptoms following a WAD usually begin in the neck and interscapular area within a few hours of the injury. Headaches ot en accompany the neck and shoulder girdle symptoms.[110]

Sources of Symptoms

T e causes for symptoms following a whiplash injury are numerous. T e resulting damage from a WAD can include an injury to one or more of the following types of structures:

- So*ft* tissue structures.[100] A cervical strain may be produced by an overload injury to the cervical muscle–tendon unit because of excessive forces. T ese forces can result in the elongation and tearing of muscles or ligaments, edema, hemorrhage, and inflammation. Many cervical muscles do not terminate in tendons but, instead, attach directly to the bone by myofascial tissue that blends into the periosteum.[352] Muscles respond to injury in a variety of ways, including reflex contraction, which further increases the resistance to stretch and serves as a protection to the injured muscle.
- Joint capsule and ligaments. Both mechanoreceptors and nociceptors have been identified in the human cervical joint capsule[353] and ligaments,[323] indicating a neural input in pain sensation and proprioception. Postmortem studies have found that at er whiplash injuries, ligamentous injuries are extremely common in the cervical spine, but that herniation of the NP is a rare event.[354–357] T e motion segment lesions found in the cervical spine included bruising and hemorrhage of the uncinate region, the so-called rim lesions or transections of the anterior annulus fibrosus, rupture of the alar ligaments, and avulsions of the vertebral end plate.[354–358] As in the lumbar spine, the outer layers of the cervical annulus are innervated,[359] and are, therefore, a reasonable source of pain.[135]
- Zygapophyseal joint. Fractures or contusions of the zygapophyseal joints can occur, although postmortem studies reveal that many of these injuries are undetectable by plain radiographs.[354,356,360,361] Zygapophysial joint pain is the only basis for chronic neck pain at er whiplash that has been subjected to scientific scrutiny.[114,362,363] However, it cannot be diagnosed clinically or by medical imaging. T e diagnosis relies on fluoroscopically guided, controlled diagnostic blocks of the painful joint. Although there is uncertainty about the exact pathway that elicits neck pain, the cervical zygapophyseal joint has been identified

as a source of pain in between 25% and 65% of people with neck pain.[114,323–325,364–366] Specifically, the prevalence of lower cervical facet joint pain has been reported to be 49%.[365] It is worth remembering that although the so-called neck sprains from MVCs usually involve the cervical spine, one of the upper eight thoracic spinal joints is sometimes found to be affected, so these structures should be assessed in the examination of a whiplash injury.[367]

- Central or peripheral neurologic systems. T ese systems may be injured secondary to traction, impingement, hemorrhage, avulsion, or concussion. Although neck pain and headache are the two most common symptoms of a whiplash injury,[263] other symptoms, such as visual disturbances, balance disorders, and altered cerebral function are reported. In 1927, Klein and Nieuwenhuyse[368] first demonstrated that simple rotation of the patient's neck, while the head was maintained fixed, caused vertigo and nystagmus. In 1976, Toglia[369] reported objective electronystagmography (ENG) abnormalities in about 57% of 309 patients with whiplash injuries. Wing and Hargrove-Wilson[370] reported that all of their 80 patients showed nystagmus in ENG records with the head flexed, extended, or rotated to the right and let . Abnormal peripheral vestibular function was found using platform posturography in about 90% of the 48 patients examined by Chester.[371] Fractures and dislocations, many causing cord damage, have been demonstrated on human victims of hyperextension injuries, who had no radiographic evidence of the severity of these lesions.[95,372]
- Intervertebral disk. Experimental and clinical studies have consistently demonstrated how poorly and slowly disk lesions heal at er a hyperextension trauma, with very small lesions taking as long as 18 months to heal.[361,373] A follow-up study, averaging a review time of nearly 11 years,[374] found that 40% of patients were still having intrusive or severe symptoms (12% severe and 28% intrusive). T e same study also found that, in general, the symptoms did not alter at er 2 years postaccident.
- Posterior (dorsal) root ganglia.[361]
- Vascular structures (vertebrobasilar arteries). Postmortem studies have shown that vertebral artery lesions are found in about one-third of fatally injured MVC victims with vertebral atlas injury.[375]
- Visceral structures (secondary to ruptures, or contusions).

T e physical examination usually reveals tenderness over the transverse and spinous processes, or over the anterior vertebral body, depending on the structures involved. Depending on the severity of the strain, motion can be markedly restricted as a result of muscle guarding.

Other than perhaps to screen for possible fractures, there is no valid indication for medical imaging at er whiplash. Findings on plain films are typically normal, although there may be a loss of the cervical lordosis. However, imaging studies can be used to assess the sot tissues. T e advent and use of higher field of MRI has allowed the identification of such findings as reductions in the size and shape of the oropharynx in subjects with chronic whiplash related disability when compared to healthy controls.[376] T ese changes may be a consequence of both changes in structure and function of the neck muscles secondary to pain and disability.[377]

Intervention

Once the physician has ruled out the possibility of a fracture, dislocation, IVD injury, or neurovascular compromise, a conservative approach is recommended. Initially, brief use of a cervical collar may be prescribed to reduce muscle guarding. Bed rest, along with analgesics and muscle relaxants, for no more than 2–3 days is prescribed for patients with a severe injury. However, in less severe cases, bed rest has not been shown to improve recovery and, when compared with mobilization or patient education, rest tends to prolong symptoms.[228,229]

CLINICAL PEARL

A study by Scholten-Peeters[378] et al. reported that the physical prognostic factors associated with delayed recovery following a WAD included decreased mobility of the cervical spine immediately after injury, preexisting neck trauma, older age, and female gender.

Ice and electrical stimulation are applied to the neck during the first 48–72 hours to help control pain and inflammation. Range-of-motion exercises in the pain-free ranges of flexion and rotation are initiated as early as possible to reduce the likelihood of hypomobility. Gentle cervical isometrics are also introduced. Aggressive strengthening of the cervical musculature should not begin until the full range of motion is restored. Strengthening of the trapezius muscle and other scapular stabilizers can be performed using upper extremity exercises, taking care to avoid an increase in symptoms.

Many patients improve within 8 weeks, although complete resolution is less common.[295] If pain persists for more than 3 months, more severe ligamentous, disk-associated zygapophyseal joint injuries, or other factors (see later) should be suspected. If significant neck pain persists past 6–8 weeks, flexion and extension radiographs may be useful to exclude or confirm instability.

Outcomes

Studies addressing the natural history of WAD have yielded variable results. In one series, symptoms had resolved in 52% of patients at 8 weeks and in 87% of the patients at 5 months.[379] In another series, most patients rapidly recovered following an acute injury, with some 80% being asymptomatic by 12 months.[337] At er 12 months, between 15% and 20% of patients remained symptomatic, and only about 5% were severely affected. In addition to the distress resulting from neck and upper extremity pain, costs to society associated with absenteeism from work are also incurred.

T e majority of studies reveal that, although most patients with WAD have a spontaneous resolution of symptoms, a small subgroup of patients are symptomatic beyond 1 year.[380] T is group of patients constitutes the major burden to insurance companies and to health care resources, because in spite of aggressive imaging and diagnostic testing, clinicians are routinely unable to identify the specific source of these symptoms

or apply interventions that are successful. It is in this small subgroup of patients with persisting chronic symptoms that the need for a better understanding of the risk factors, pathophysiology, natural history, and effectiveness of intervention options is apparent.[380]

When symptoms persist beyond 6 months, evidence of preexisting degenerative disease is most ot en found.[380] Preexisting symptoms, such as a headache, and degenerative radiologic changes appear to be important predictors of an unfavorable outcome.[123]

One study[337] examined a group of 117 consecutive patients, who were followed on a regular basis from shortly at er the initial injury through 2 years, to determine whether preinjury status, mechanism of injury, physical examination, and somatic, radiographic, or neuropsychologic factors could be used to predict eventual outcome. At 2 years, the patients with persistent symptoms were found to have been older at the time of injury than the asymptomatic group and had a higher incidence of a pretraumatic headache. T ere was a higher incidence of a rotated, or inclined, head position at the time of impact, as well as a higher intensity of initial neck pain and headache, a higher incidence of initial radicular symptoms, a greater number of initial overall symptoms, and a higher average score on a multiple symptom analysis.[337]

Financial compensation, which is determined by the continued presence of pain and suffering, appears to provide a barrier to recovery and may promote persistent illness and disability. T e incidence of insurance claims for whiplash is about 1 per 1000 population per year,[362] yet not all persons involved in motor vehicle crashes develop symptoms, and not all symptomatic patients experience chronic injury. T e differences in the rating of prolonged symptoms between systems with and without compensation raise questions about the real incidence of chronic WADs.[381]

INTEGRATION OF PATTERNS 4B, 4F, AND 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION SECONDARY TO IMPAIRED POSTURE, SYSTEMIC DYSFUNCTION (REFERRED PAIN SYNDROMES), SPINAL DISORDERS, MYOFASCIAL PAIN DYSFUNCTION, AND PERIPHERAL NERVE ENTRAPMENT

Thoracic Outlet Syndrome

T e thoracic outlet is the anatomic space bordered by the first thoracic rib, the clavicle, and the superior border of the scapula, through which the great vessels and nerves of the upper extremity pass (Fig. 25-4). T e bony boundaries of the outlet include the clavicle, first rib, and scapula, and the outlet passage is further defined by the interscalene interval, a triangle with its apex directed superiorly. T is triangle is bordered anteriorly by the anterior scalene muscle, posteriorly by the middle scalene muscle, and inferiorly by the first rib (see Fig. 25-4). TOS is a syndrome characterized by symptoms attributable to compression of the neural or vascular structures that pass through the thoracic outlet.[193,382]

T e other names used for TOS are based on descriptions of the potential sources of its compression. T ese names include cervical rib syndrome, scalenus anticus syndrome, hyperabduction syndrome, costoclavicular syndrome, pectoralis minor syndrome, and first thoracic rib syndrome.

TOS was first noted in 1743 when an association was made between the cervical rib and TOS, although it was not until 1818 that the medical management of TOS was discussed.[383] In the early 20th century, Adson stressed the role of the scalene muscles in neurovascular compromise, and Wright showed that shoulder hyperabduction could produce thoracic outlet obstruction.[383] It was Peet[384] who coined the term "TOS" in 1956. T en, in the early 1960s, Roos[65] emphasized the importance of the first rib and its muscular and ligamentous attachments in causing thoracic outlet obstruction.

T e lowest trunk of the brachial plexus, which is made up of rami from the C8 and T1 nerve roots, is the most commonly compressed neural structure in TOS. T ese nerve roots provide sensation to the fourth and fit h fingers of the hand and motor innervation to the intrinsic hand muscles.

T e subclavian artery and the lower trunk of the plexus pass behind the clavicle, and into the costoclavicular space (see Fig. 25-4). From there they pass over the first rib, between the insertions of the anterior and middle scalene muscles and are joined by the subclavian vein.

T us, the course of the neurovascular bundle can be subdivided into three different sections, based on the areas of potential entrapment:

1. As the brachial plexus and subclavian artery pass through the interscalene triangle (see Fig. 25-4), interscalene triangle compression can result from injury of the scalene or scapular suspensory muscles. In some cases, fibromuscular bands can develop between the anterior and middle scalenes, or between the long transverse processes of the lower cervical vertebrae, producing entrapment. T e subclavian vein is not involved, because it usually passes anterior to the anterior scalene muscle. Entrapment at this site may also result from cervical ribs, which are present in 0.2% of the population and occur bilaterally in 80% of those affected.[65] However, the presence of a cervical rib does not necessarily precipitate signs and symptoms, with fewer than 10% of individuals with cervical ribs ever experiencing TOS.[65]
2. As it passes the first rib, clavicle, and subclavius: the costoclavicular interval. Entrapment in this space between the ribcage and the posterior aspect of the clavicle may occur with clavicle depression, rib elevation caused by scalene hypertonicity, repetitive shoulder abduction, or a first rib-clavicular deformity. A postfracture callus formation of the first rib or clavicle can also increase the potential for entrapment.
3. As it passes the coracoid process, pectoralis minor, and clavipectoral fascia to enter the axillary fossa. At this point, the subclavian artery and vein become the axillary artery and vein. At this third site, the neurovascular bundle can be compromised with arm abduction or elevation, especially

if external rotation is superimposed on the motion. Pectoralis minor tendon compression is associated with shoulder hyperabduction. During hyperabduction, the tendon insertion and the coracoid act as a fulcrum, about which the neurovascular structures are forced to change direction. Hypertrophy of the pectoralis minor tendon has also been noted as a cause of outlet compression.[383]

T ere may be multiple points of compression of the peripheral nerves between the cervical spine and hand, in addition to the thoracic outlet. When there are multiple compression sites, less pressure is required at each site to produce symptoms. T us, a patient may have concomitant TOS, ulnar nerve compression at the elbow, and carpal tunnel syndrome. T is phenomenon has been called the multiple crush syndrome.[385]

Symptoms vary from mild-to-limb threatening and ot en mimic common but dif cult to treat conditions, such as a tension headache or fatigue syndromes. T e chief complaint is usually one of diffuse arm and shoulder pain, especially when the arm is elevated beyond 90 degrees. Potential symptoms include pain localized in the neck, face, head, upper extremity, chest, shoulder, or axilla; and upper extremity paresthesias, numbness, weakness, heaviness, fatigability, swelling, discoloration, ulceration, or Raynaud phenomenon.[382] Neural compression symptoms occur more commonly than vascular symptoms.[65]

Karas[386] described five symptom patterns of TOS, characterized by the primary structures compressed.

1. T e lower trunk pattern reflects lower plexus compression and manifests with pain in the supraclavicular and infraclavicular fossa, back of the neck, rhomboid area, axilla, and medial arm and may radiate into the hand and fourth and fit h fingers. T e history includes reports of feelings of coldness, or electric shock sensations in the C8–T1 or ulnar nerve distributions.
2. T e upper trunk pattern results from upper plexus compression and is distinguished by pain in the anterolateral neck, shoulder, mandible, and ear, and paresthesias that radiate into the upper chest and lateral arm in the C5–7 dermatomes.[386,387]
3. With venous involvement, the signs and symptoms can include swelling of the entire limb, nonpitting edema, bluish discoloration, and venous collateralization across the superior chest and shoulder.
4. Arterial involvement produces coolness, ischemic episodes, and exertional fatigue.[386]
5. T e mixed pattern consists of a combination of vascular and neurologic symptoms.[386]

Illig et al.[388] simplify the classification by defining TOS as three separate entities:

1. Neurogenic TOS. Compression of the brachial plexus at the scalene triangle. Symptoms, which include either local or extremity pain, are ot en exacerbated by lit ing the arms overhead. T is type may account for about 95% of the cases.
2. Venous TOS. Compression of the subclavian vein by the structures making up the costoclavicular junction. T is type may account for about 4% of the cases.
3. Arterial TOS. Compression due to abnormal bony or ligamentous structures at the thoracic outlet region.

Mechanisms

Proposed mechanisms for TOS are as follows:

- *T*raumatic. Twenty-one percent to 75% of TOS patients have an association with trauma.[387] T is may involve macrotrauma, as in the case of an MVC, or microtrauma, as in the case of a muscle strain of the scapular stabilizers, resulting from repetitive overhead activities.[389–391]
- Developmental. During the normal growth of children and adolescents, the scapulae gradually descend upon the posterior thorax, with the descent being slightly greater in women than in men. A strain injury to the scapular suspensory muscles, which lengthen in conjunction with scapular descent during normal development, is known to be associated with TOS. T ese facts help to explain the rarity of symptomatic TOS until at er puberty, and the increased prevalence in women.[193,392]

Diagnosis

TOS is a clinical diagnosis, made almost entirely on the basis of the history and physical examination (see section "Special Tests"). To help rule out other conditions that can mimic TOS, the physical examination should include the following:

- A careful inspection of the spine, thorax, shoulder girdles, and upper extremities for postural abnormalities, shoulder asymmetry, muscle atrophy, excessively large breasts, obesity, and drooping of the shoulder girdle.
- Palpation of the supraclavicular fossa for fibromuscular bands, percussion for brachial plexus irritability, and auscultation for vascular bruits that appear by placing the upper extremity in the position of vascular compression.
- Assessment of the neck and shoulder girdle for active and passive ranges of motion, areas of tenderness, or other signs of intrinsic disease.
- A thorough neurologic examination of the upper extremity, including a search for sensory and motor deficits and abnormalities of muscle stretch reflexes.
- Assessment of respiration to ensure the patient is using correct abdominodiaphragmatic breathing.
- Assessment *of* the suspensory muscles. T e middle and upper trapezius, levator scapulae, and SCM (thoracic outlet "openers"). T ese muscles are typically found to be weak.
- Assessment *of* the scapulothoracic muscles. T e anterior and middle scalenes, subclavius, pectoralis minor and major (thoracic outlet "closers"). T ese muscles typically are found to be adaptively shortened.
- First rib position or presence of cervical rib.
- Clavicle position and history of prior fracture, producing abnormal callous formation or malalignment.
- Scapula position, acromioclavicular joint mobility, and sternoclavicular joint mobility.
- Neurophysiologic tests, which are useful to exclude coexistent pathologies such as peripheral nerve entrapment or cervical radiculopathy. An abnormal reflex F-wave conduction and decreased sensory action potentials in the medial antebrachial cutaneous nerve may be diagnostic.[393]

Intervention

Conservative intervention should be attempted before surgery and should be directed toward muscle relaxation, relief of inflammation, and attention to posture. T is intervention approach may require a change of occupation for the patient because TOS is more common in those who stoop at work. Aggressive physical therapy, particularly traction, may worsen symptoms.[394]

T e focus of the intervention is the correction of postural abnormalities of the neck and shoulder girdle, strengthening of the scapular suspensory muscles, stretching of the scapulothoracic muscles, and mobilization of the whole shoulder complex and the first and second ribs.

Kenny et al.[395] prospectively evaluated a group of eight patients, composed mainly of middle-aged women, whose TOS was treated with a supervised physical therapy program of graduated, resisted shoulder elevation exercises.[193] All patients showed major symptomatic improvement.

If symptoms progress or fail to respond within 4 months, surgical intervention should be considered.[396] Lower plexus TOS is surgically treated by first rib and (if present) cervical rib excision.[397] Although it has been suggested that the insured patient is more likely to have an operation, results are independent of any associated litigation.[398]

THERAPEUTIC TECHNIQUES

Techniques to Increase Joint Mobility

Joint Mobilizations

Most joint mobilizations use the same technique as the assessment but, by using grades, convert it into a treatment method. T e purpose of joint mobilization techniques is to

- reduce stresses through both the fixation and the leverage components of the spine;
- reduce stresses through hypermobile segments by mobilizing the hypomobile joints;
- reduce the overall force needed by the clinician, thus giving greater control.

T e selection of a manual technique is dependent on several factors, including the following:

- T e acuteness of the condition, the cause of the restriction, and the goal of the intervention. If the structure is acutely painful (pain is felt before resistance or pain is felt with resistance), pain relief, rather than a mechanical effect, is the major goal. Joint oscillations (grades I and II) that do not reach the end of the range are used. T e segment or joint is let in its neutral position, and the mobilization is carried out from that point.
- Whether the restriction is symmetric, involving both sides of the segment, or asymmetric, involving only one side of the segment.

A number of specific manual techniques can be employed. Spinal locking techniques can be used to augment the comfort and safety of a manual technique. Locking is simply a method of taking up any available sot tissue tension or slack, thereby making a manual technique more specific. Two types of locking techniques are commonly advocated: craniovertebral locking and locking through segmental translation. Because of the potential for vertebral artery compromise in the craniovertebral region, the craniovertebral joints are ot en "locked" first before continuing motion into the middle and/or lower cervical spine joints. In the following example, a let side-bending technique is used. Although this locking technique may be used with the patient positioned in sitting or supine, if it used in supine it is important to apply a small amount of compression to compensate for the loss of the spinal loading due to the weight of the head.

While palpating the C2 spinous process, the clinician slowly side-bends the patient's head to the let . If the side bending is performed around a sagittal craniovertebral axis, the C2 spinous process should be felt to move to the right, indicating let rotation of the C2 on the C3. Maintaining the let side-bent position, the head is now rotated to the right until the C2 spinous process regains a central position. T e head is again side-bent slightly to the let , and the C2 spinous process de-rotated back to the midline. T ese motions are continued until a firm end-feel is reached. At this point, motion in the craniovertebral joints has now been exhausted, while the rest of the cervical joints remain in neutral. Being careful to maintain the position of the head, especially the right rotation, the side bending is continued let to the middle or lower cervical level required. As the cervical joints are prevented from rotating to the let , the middle cervical side-bending motion is exhausted very quickly.

T e vast majority of biomechanical dysfunctions of the cervical spine involves the posterior quadrant (a loss of extension and a loss of side bending and rotation to one side or both). T e loss of cervical flexion is usually associated with a cervical disk protrusion, a cervicothoracic dysfunction, or a craniovertebral dysfunction. However, for completeness, the techniques described here will address a loss in both the anterior and the posterior quadrants.

T e C4–5 level is used in the following examples. T e midrange is considered the biomechanical neutral resting position of the joint, and is the ideal start point for techniques that are not intended to stress the barrier and that are intended to avoid causing pain or increasing inflammation. T e various methods of grading manual therapy techniques are described in Chapter 10.

Basic Techniques to Restore Motion in the Posterior Quadrant

Seated Mobilization Technique to Restore Extension and Left Side-Bending Rotation

VIDEO

If the clinician has large hands, mobilizing into extension can be a problem because the stabilizing hand prevents the full glide into extension from occurring. To overcome this problem, the stabilization of the inferior segment is performed by pushing the thumb up against the side of its spinous process, thereby preventing the rotation induced by the mobilization of the superior segment. For example, if the let side of C4–5 is being mobilized into extension, let side bending, and let rotation by the upper hand, the thumb of the inferior hand is

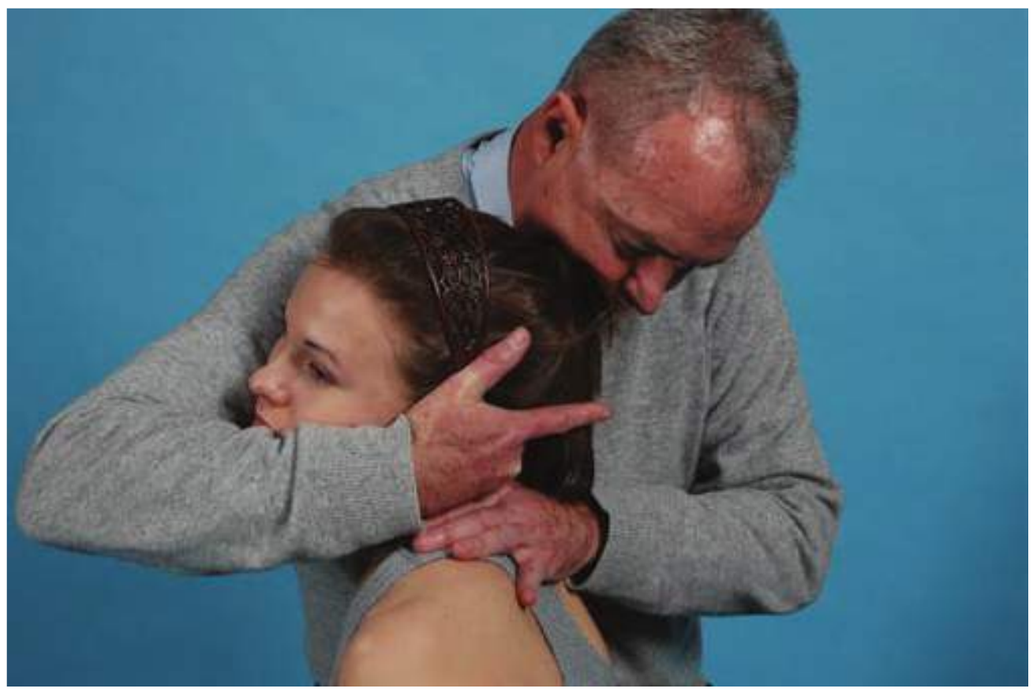

FIGURE 25-83 Seated mobilization to increase extension and left rotation.

pushed against the right side of the C5 spinous process, preventing rotation of C5 to the let (Fig. 25-83).

Supine Mobilization Technique to Restore Extension and Left Side-Bending Rotation (Left Side-Bending Rotation shown on VIDEO)[166]

The patient is positioned supine, with the head being supported. The clinician stands at the patient's head, facing the shoulders. With the radial aspect of the right index finger, the clinician palpates the spinous process and the right inferior articular process of the C4 vertebra. With the other hand, the clinician supports the head and neck superior to the level being treated (Fig. 25-84). A lock of the superior segment is accomplished by let side bending and right rotating the C3–4 joint complex, leaving the craniovertebral joints in a neutral position. The motion barrier for extension, let side bending, and let rotation of C4–5 is then localized by pushing the right inferior articular process of C4 in a posteroinferior and medial direction on C5.

- Passive. The clinician applies a grade I–V force to the C4 vertebra to produce a posteroinferior and medial glide of the let zygapophyseal joint at C4–5.
- Active. From the motion barrier, the patient is asked to turn the eyes in a direction that facilitates further extension, let side bending, and right rotation. The isometric contraction is held for up to 5 seconds and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. The technique is repeated three times and followed by a reexamination of joint function.

Basic Techniques to Restore Motion in the Anterior Quadrant

Seated Mobilization Technique to Restore Flexion and Right rotation (Rotation Right Side-Bending Rotation shown on VIDEO)

The patient is positioned sitting, and the clinician stands on the right side. Using one hand, the clinician stabilizes the C5 segment using a lumbrical grip (Fig. 25-85). The other hand reaches around the head of the patient, securing it to the clinician's chest, and the ulnar border of the fit h finger is applied

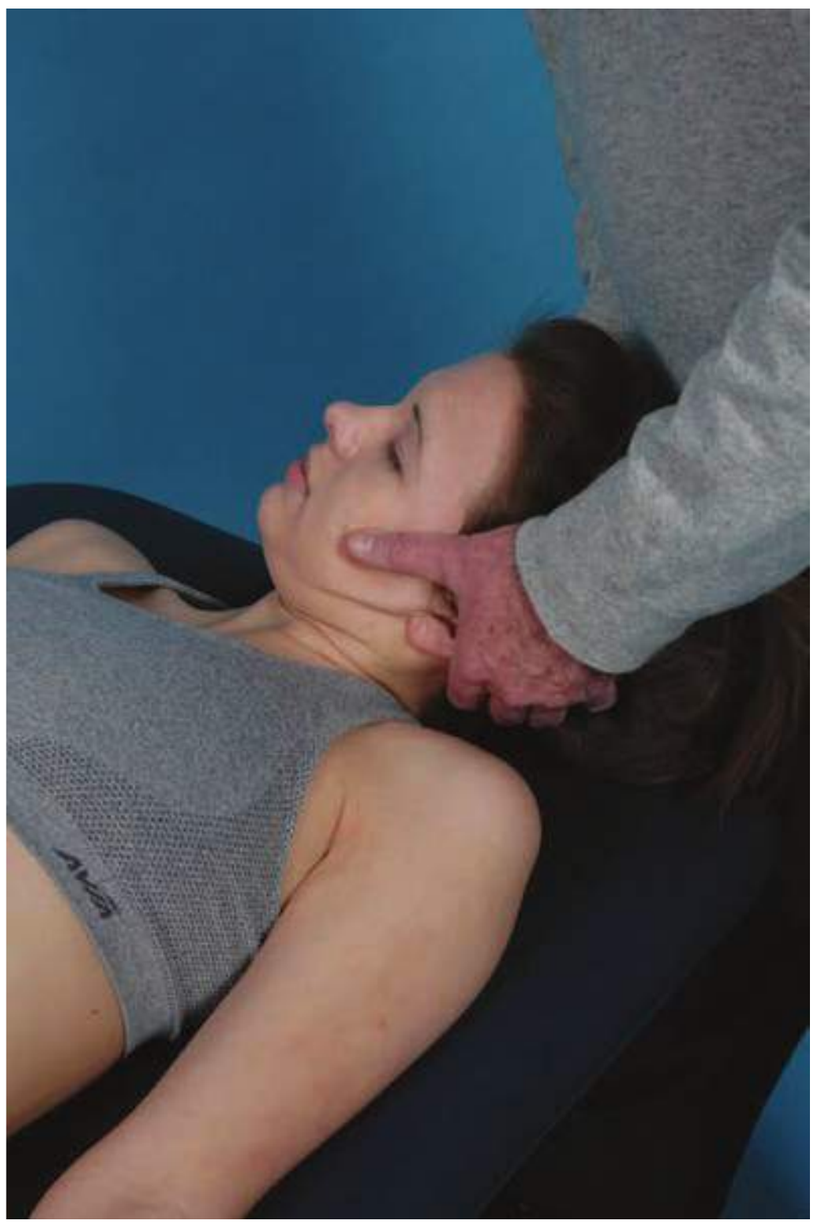

FIGURE 25-84 Supine mobilization technique to restore extension and left side bending rotation.

to the let transverse process and neural arch of C4. The C4–5 segment is then flexed and rotated to the right to the barrier (see Fig. 25-85). The mobilization is carried out by the clinician applying pressure into flexion and right rotation.

- Passive. A grade I–IV mobilization force is applied to the C4 vertebra to produce a superoanterior glide at the zygapophyseal joints, thus flexing the C4–5 joint complex and feeling the spinous processes separate.
- Active. At the motion barrier, the patient is instructed to turn the eyes in a direction that facilitates further flexion at C4–5. The isometric contraction is held for up to 5 seconds and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. The technique is repeated three times and followed by a reexamination of joint function.

FIGURE 25-85 Seated mobilization into flexion and right rotation.

FIGURE 25-86 Supine mobilization technique to restore flexion and left side bending rotation.

FIGURE 25-87 Seated technique for the cervicothoracic junction.

Supine Mobilization Technique to Restore Flexion and Right Side-Bending Rotation (Left Side-Bending Rotation shown on VIDEO)

The patient is positioned supine, with the head being supported. The clinician stands at the head of the table facing the patient. The C4–5 segment is flexed, right side bent, and let translated to bring the right joint to its flexion barrier. The clinician hooks a fingertip under the right articular process and lays a fingertip pad over the articular process on the right (see Fig. 25-86). The mobilization is achieved by pulling the left process cranially, as steady light pressure is applied to the back of the left process to maintain a normal axis of motion.

- Passive. A grade I–V mobilization force is applied to the C4 vertebra to produce a superoanterior and medial glide of the right zygapophyseal joint at C4–5.
- Active. At the motion barrier, the patient is instructed to turn the eyes in a direction that facilitates further flexion, right side bending, and rotation at C4–5. The isometric contraction is held for up to 5 seconds and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. This technique is repeated three times and followed by a reexamination of function.

Techniques to Restore Motion in Bilateral Extension Hypomobility

Bilateral hypomobilities can be treated with unilateral techniques performed to each side when only the last part of the range of movement is absent.

Seated Technique for the Cervicothoracic Junction

The patient is seated with the arms behind the head. The clinician stands in front of the patient and threads the arms through the patient's arms, before resting both of the hands on the top, and back, of each of the patient's shoulders (Fig. 25-87). By gently leaning the patient forward, the cervical spine is extended until the stiff segment is located at the cervicothoracic junction. Gradually, the clinician increases the amount of cervicothoracic extension by gently kneading the midscapular area. Distraction, side flexion, or rotation motions can also be introduced. Care should be taken to avoid overextending the lumbar spine during this technique, by pulling the patient too far forward.

Mobilizations with Movement

To Improve Flexion

The patient is positioned sitting, with the clinician standing to the side, facing the patient.[399] The patient's head is held in neutral against the clinician's lower chest, and the distal phalanx of the little finger is hooked under the spinous process of the superior vertebra of the segment being treated. The rest of the fingers wrap around the patient's neck to provide firm support, and the wrist is extended, with the forearm placed in the plane of the facets. The lateral border of the thenar eminence of the other hand is placed below the little finger (see Fig. 25-88), and the palm of the hand rests on the upper back of the patient.

The patient is asked to flex the neck, and the glide of the superior segment is produced along the correct plane by a

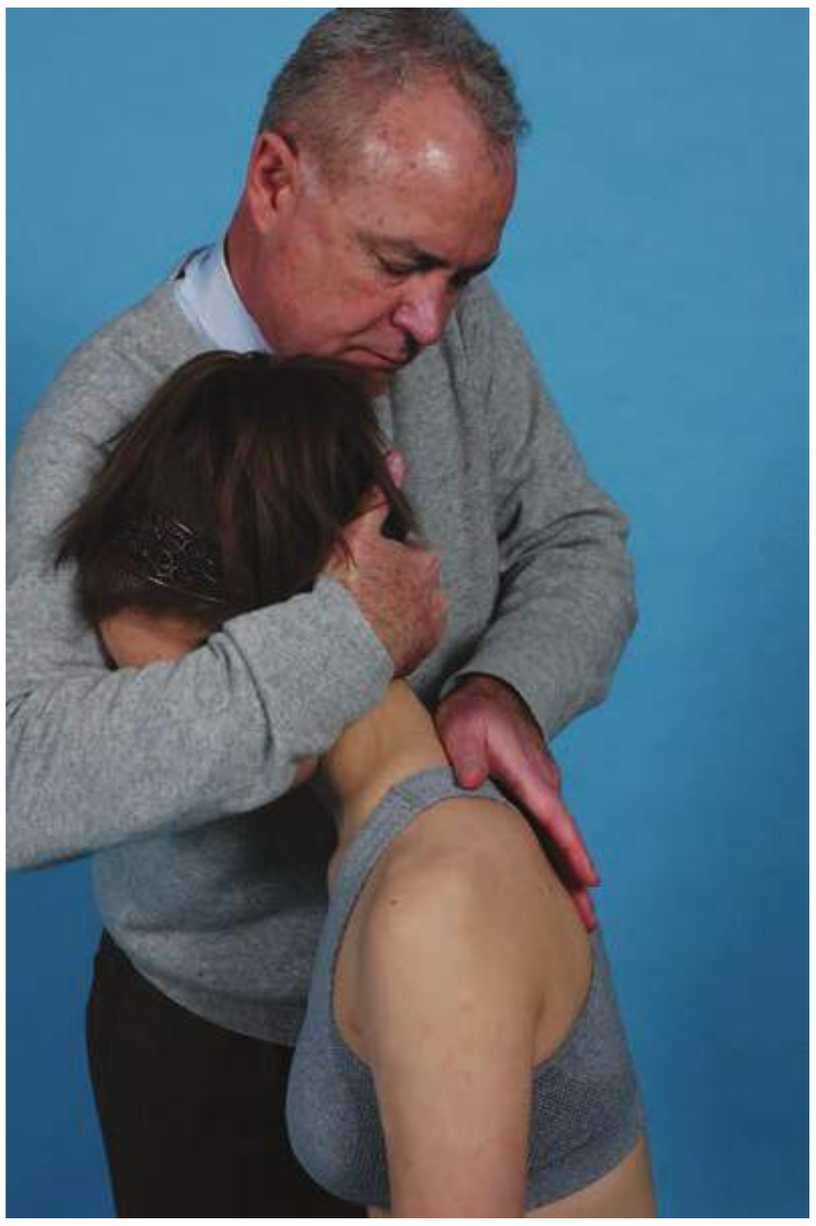

FIGURE 25-88 Mobilization with movement to improve cervical flexion.

FIGURE 25-89 Mobilization with movement to improve cervical extension.

pull from the little finger in an anterior and superior direction, while the other hand stabilizes the lower segment.

This technique can be taught as part of the patient's home exercise program using a towel, belt, or strap.

To Improve Extension

The patient is positioned sitting, with the clinician standing to the side, facing the patient. The patient's head is held in neutral against the clinician's lower chest, and the distal phalanx of the little finger is hooked under the spinous process of the superior vertebra of the segment being treated. Using a key grip between the index finger and thumb, the clinician places the grip over the articular pillar on either side of the inferior spinous process of the segment (Fig. 25-89).

The patient is asked to extend the neck while the clinician simultaneously applies a glide of the inferior vertebra by pushing with the key grip hand.

This technique can be taught as part of the patient's home exercise program using a towel, belt, or a strap.

To Improve Rotation to the Right

The patient is positioned sitting, with the clinician sitting behind. The clinician places the thumb of one hand over the articular pillar over the right aspect of the spinous process of the superior vertebra of the segment to be treated. The other thumb is placed over the first thumb to help reinforce. The remaining fingers of the two hands are placed around the neck and upper back.

The patient is asked to rotate the head and neck slowly to the right while the clinician simultaneously applies the glide along the correct joint plane using pressure from both thumbs (see Fig. 25-90). The same technique can be used to improve cervical rotation to the right by altering the position of the thumbs.

This technique can be taught as part of the patient's home exercise program using a towel, belt, or a strap (Fig. 25-91).

Techniques to Increase Soft Tissue Extensibility

A variety of soft tissue techniques for the cervical region is available to the clinician. The choice of technique depends on the goals of the treatment and the dysfunction being treated.

Myofascial Trigger Point Therapy

Ischemic compression is advocated for myofascial trigger points and is achieved by sustaining direct pressure over a

FIGURE 25-90 Mobilization with movement to improve cervical rotation to the left.

FIGURE 25-91 Home exercise to improve cervical rotation to the left.

trigger point, using the thumb to apply pressure.[295] The pressure is held for 5–7 seconds and then quickly withdrawn.[400] The procedure is repeated for each trigger point. After each trigger point has been treated, the clinician returns to the first trigger point. The procedure is repeated three times on each trigger point.[400]

To facilitate self-treatment for inaccessible regions, such as the rhomboid muscles, lying on a tennis ball, or using the handle of a cane can be substituted for direct manual compression.[295]

Muscle Stretching

Pectoralis Minor

The pectoralis minor can be stretched effectively using a corner and placing the forearms on the walls. The patient needs to avoid adopting a forward head posture during the stretch. The patient attempts a contraction of horizontal abduction and internal rotation into the wall. The clinician is cautioned against using this exercise with any patient with shoulder pathology, especially an anterior instability.

Pectoralis Major

The pectoralis major can be specifically stretched if the orientation of its fibers is considered (clavicular and costosternal), by having the patient lie supine and extending the arm off the table in either approximately 140 degrees of shoulder abduction (costosternal fibers) or approximately 45–50 degrees of abduction (clavicular fibers) (see Fig. 25-92).

For the following muscles, the same technique that is used to assess the length of this muscle is used for the stretch:

Sternocleidomastoid

The SCM functions to flex and rotate the neck and extend the occipitoatlantal joint. The patient is positioned in sitting or supine (see Fig. 25-37). The patient is positioned supine, with the head supported. From this position, the clinician induces side bending of the neck to the contralateral side and extension of the neck. The clinician stabilizes the scapula and rotates the patient's head and neck toward the ipsilateral side.

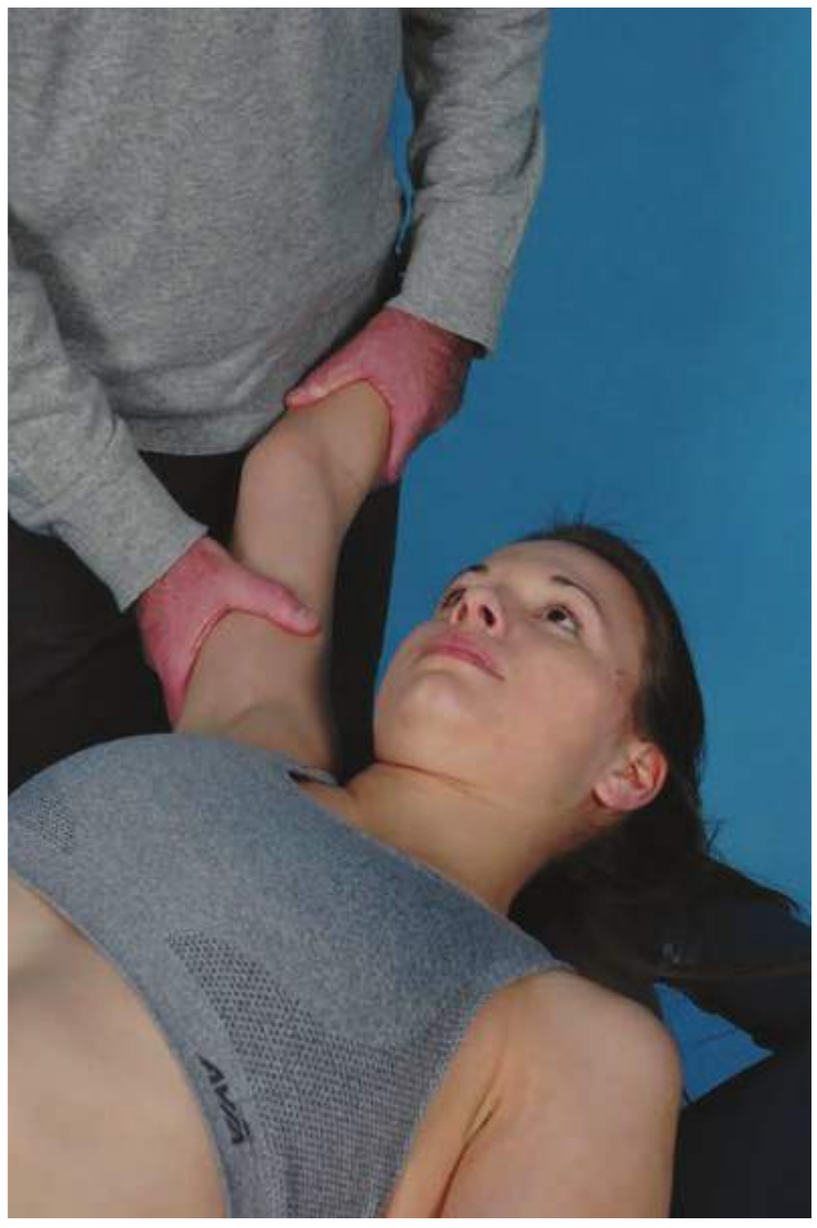

FIGURE 25-92 Pectoralis major stretch of the costosternal fibers.

Anterior and Middle Scalenes

The patient is positioned in supine. After stabilizing the first two ribs with the heel of one hand, the clinician performs passive cervical extension, contralateral side bending, and ipsilateral rotation (see Fig. 25-38).

Levator Scapulae

The stretch can be passively applied by the clinician. The patient is positioned supine, with the head at the edge of the table. The elbow and hand of the side to be treated are placed on the head. The clinician stands at the head of the table and presses his or her thigh against the point of the patient's elbow, fixing it caudally. Using both hands, the clinician then flexes the neck and side flexes the patient's head to the opposite side, until resistance is felt. The patient is then asked to look toward the treated side, a motion that is resisted by the clinician. When the patient relaxes, the clinician moves the head into further side flexion and flexion.

Upper Trapezius

This procedure is similar to that of the levator scapulae except that the amount of neck flexion is reduced (see Fig. 25-34). The patient is positioned supine, with the head at the edge of the table. Using both hands, the clinician then flexes the neck and side bends the patient's head to the opposite side. Rotation to the ipsilateral side is then added until resistance is felt. The patient is then asked to look toward the treated side, a motion that is resisted by the clinician. When the patient relaxes, the clinician moves the head into further flexion, side bending, and rotation.

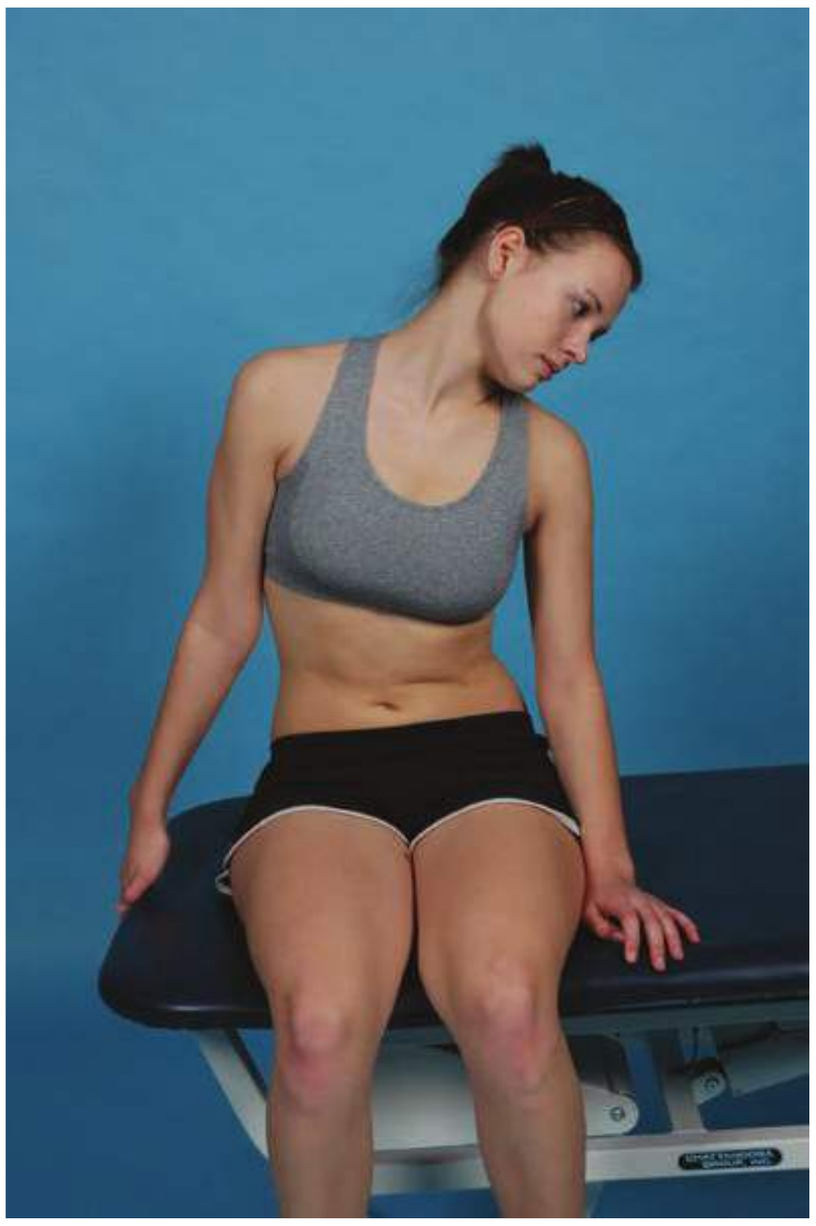

FIGURE 25-93 Self-stretch of levator scapulae.

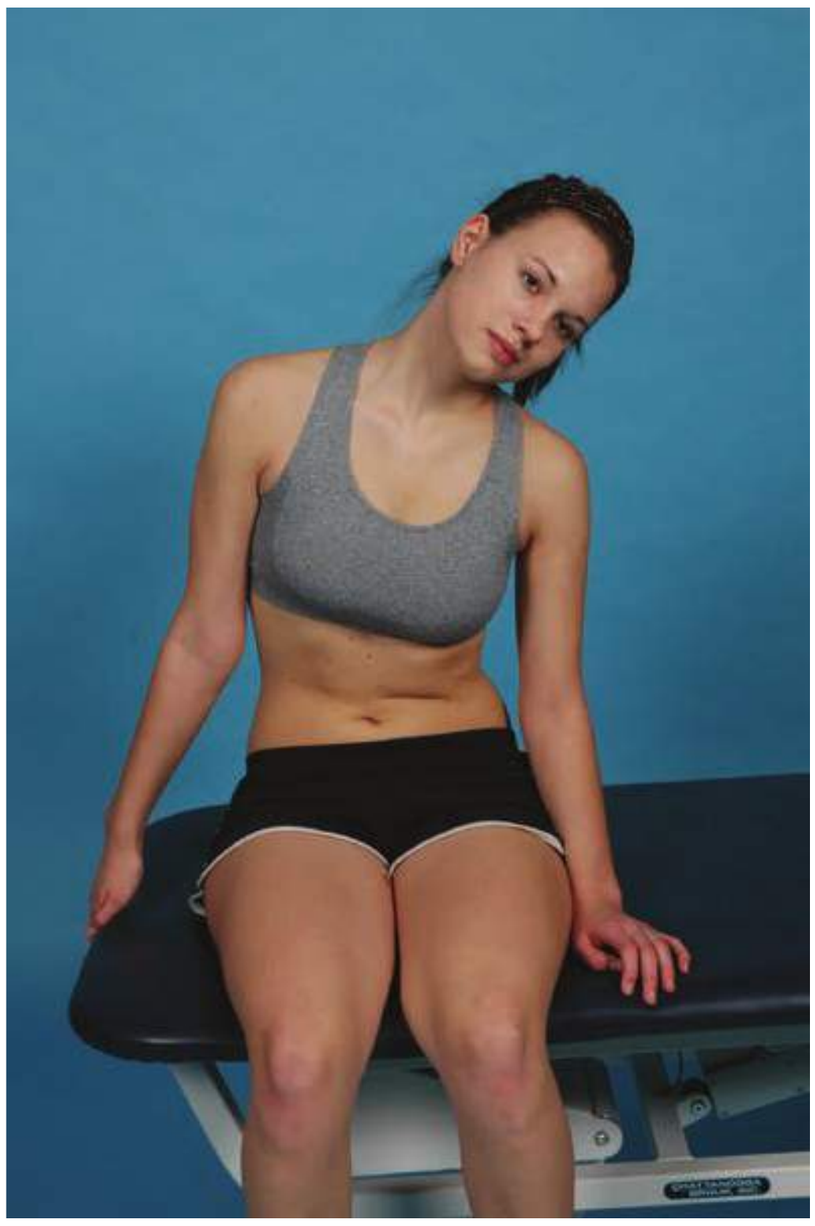

FIGURE 25-94 Self-stretch of upper trapezius.

In addition to the muscles described here, the clinician should assess the following muscles for adaptive shortening:

- Rectus capitis posterior major;
- Rectus capitis posterior minor;
- Obliquus capitis inferior; and
- Obliquus capitis superior.

T e stretches for these muscles are described in Chapter 23.

Self-Stretching Techniques

Levator Scapulae

T e patient is seated in good posture. T e patient flexes the neck fully and then side bends the head while maintaining the neck flexion (see Fig. 25-93). T e side bending continues until a gentle stretch is felt. Gentle overpressure can be applied using one hand. T e stretch is maintained for 8–10 seconds and then the patient relaxes. T e stretch is repeated 10 times.

Upper Trapezius

T e self-stretch of the right upper trapezius depicted in Figure 25-94 is described.[401] T e stretch is maintained for 8–10 seconds, and then the patient relaxes. T e stretch is repeated 10 times.

Three-Finger Exercise

Active range of motion in the cervical spine can be increased through patient participation, using the three-finger exercise.[402] T e patient's mandible rests on digits two, three, and four. T e motions of flexion (Fig. 25-95), side bending (Fig. 25-96),

FIGURE 25-95 Three-finger exercise into cervical flexion.

FIGURE 25-96 Three-finger exercise into cervical side bending.

FIGURE 25-97 Three-finger exercise into cervical rotation.

FIGURE 25-98 Active exercise into cervical extension.

and rotation (Fig. 25-97) can all be performed. An alternative method uses the index finger placed between the chin and the sternum to control the correct amount of flexion, with the PIP placed on the superior aspect of the manubrium and the tip of the index finger on the chin.

The patient is cautioned against reproducing sharp pain while attempting to feel a stretch at the end of the available motion.

With a different hand position, cervical extension can be performed in a controlled and safe manner. The fingers are interlocked and placed behind the neck, with the little fingers at the lowest segmental level of the joint restriction (at C5 for a C4–5 restriction). Using the little finger as a fulcrum, the patient extends the cervical spine to the point just shy of pain. This position is held for a few seconds, and the neck is returned to the neutral position (Fig. 25-98).

CASE STUDY

Neck Pain and Paresthesia

HISTORY

A 21-year-old woman presented to the clinic with complaints of right neck and shoulder pain, and paresthesias that often radiated into the medial arm, forearm, and fourth and fifth fingers of the right upper extremity. The patient also reported that her right upper extremity often felt tired and heavy and that her right hand occasionally would appear to have a weak grip. The patient reported that her symptoms began shortly after she was involved in an MVA about 2 months previously and have increased slightly since that time. The patient denied any history since the accident of dizziness, tinnitus, blurred vision, or headaches. No left-sided neck pain or left upper extremity symptoms were reported.

The patient described her overall health as good. Her past medical history was unremarkable, and there was no past history of any surgeries.

Questions

1. What are some of the potential causes for upper extremity paresthesias? Can you rule out any of these causes from the history given? What further questions would you ask to help rule out some of the causes?
2. Which conditions could be associated with a weak grip? Could you rule these in or out with the history?
3. Which conditions could be associated with a report of a tired and heavy upper extremity? How would you rule these in or out?
4. Would the results from any imaging studies be helpful in this case? If so, which ones and why?
5. Is an upper quarter scanning examination warranted in this case? Why or why not?
6. Is this an irritable condition? Why or why not?
7. What type of conditions were the questions about dizziness, tinnitus, blurred vision, and headaches designed to help rule out?

CASE STUDY

Low neck pain

HISTORY

A 33-year-old woman presented with a diagnosis of low neck and upper back pain that, over the past few weeks, had become constant. Initially, the pain had been minimal, but it had worsened progressively. The pain was localized to the midline at the base of the neck, and there was no report of arm pain or symptoms. The patient worked as a computer operator for a local bank. Sleeping had become difficult, and all motions of the neck were reported to reproduce the symptoms. The patient denied any dizziness or nausea, or history of neck trauma.

The patient described her overall health as excellent. The past medical history was unremarkable.

Questions

1. Make a list of all the possible causes of midline neck pain.
2. What could the gradual onset of the pain tell the clinician?
3. What is your working hypothesis at this stage? List the tests you would use to rule out the various causes of midline neck pain.
4. Should the reports of night pain concern the clinician?
5. Does this presentation/history warrant a Cyriax upper quarter scanning examination? Why or why not?

CASE STUDY

Bilateral arm and wrist weakness

HISTORY

A 36-year-old man who sustained a left tibial plateau fracture presented at the clinic with complaints of bilateral arm and wrist weakness that had worsened progressively over the past month since his discharge from the hospital. The patient was ambulating with crutches and non–weight-bearing on the left side. There was no history of cervical trauma. The patient reported no pain in his upper extremities but had noticed a mild and vague numbness in his hands. There was no report or evidence of a preceding viral infection and no proximal migration of the weakness, nor did he have any other areas of weakness. The patient did complain of pain in his axillae, and commented that his crutches had been rubbing against his axillae.[397]

Questions

1. What structure(s) could be at fault when weakness is the major complaint?
2. Why was the history of no cervical trauma pertinent?
3. Why was the statement about preceding viral infection pertinent?
4. Why was the statement about the proximal migration of the weakness pertinent?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with bilateral arm numbness and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scanning examination? Why or why not?

CASE STUDY

right-sided neck pain

HISTORY

A 45-year-old woman awoke with right-sided neck pain 10 days earlier. The pain was felt over the right neck on an intermittent basis. She related that the pain was worse with head turning to the right, and further aggravated with activities involving cervical extension. She described no neurologic pain or paresthesia. The pain sites and intensity were unchanged since the onset.

Further questioning revealed that the patient was otherwise in good health and had no reports of bowel or bladder impairment, night pain, dizziness, or radicular symptoms.

Questions

1. What structure(s) could be at fault with complaints of right-sided neck pain?
2. What should the motion pattern of restriction/pain tell you?
3. What is your working hypothesis at this stage? List the various diagnoses that could present with right-sided neck pain and the tests you would use to rule out each one.
4. What do the questions about night pain and dizziness pertain to?
5. Does this presentation/history warrant a scanning examination? Why or why not?

CHAPTER 26

The Temporomandibular Joint

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the temporomandibular joint (TMJ), including the bones, ligaments, muscles, and blood and nerve supply.
2. Describe the biomechanics of the TMJ, including the movements, normal and abnormal joint barriers, kinesiology, and reactions to various stresses.
3. Summarize the various causes of temporomandibular dysfunction (TMD).
4. Describe the close association between the TMJ, the middle ear, and the cervical spine.
5. Perform a comprehensive examination of the temporomandibular musculoskeletal system, including palpation of the articular and soft-tissue structures, specific passive mobility, and passive articular mobility tests, and stability tests.
6. Evaluate the total examination data to establish a diagnosis.
7. Recognize the manifestations of abnormal TMJ function and develop strategies to correct these abnormalities.
8. Apply active and passive mobilization techniques to the TMJ, using the correct grade, direction, and duration.
9. Describe and demonstrate intervention strategies and techniques based on clinical findings and established goals.
10. Evaluate the intervention effectiveness in order to progress or modify an intervention.
11. Plan an effective home program and instruct the patient in this program.

OVERVIEW

Approximately 50–75% of the general population has experienced unilateral temporomandibular joint dysfunction (TMD) on a minimum of one occasion and that at least 33% have reported a minimum of one continuing persistent symptom.[1,2] TMD is a collective term used to describe a number of related disorders affecting the stomatognathic system and its related structures, all of which may have common symptoms. The term *T*MJ dys*f*unction as an overall descriptor of stomatognathic system dysfunction has been discontinued because it implies structural problems when none may exist, and does not include the many other factors that may be involved.[3]

Housed within the skull are the components of the stomatognathic system, which includes the TMJ, the masticatory systems, and the related organs and tissues such as the inner ear and salivary glands.[4] An interrelationship exists between the stomatognathic system and the head and neck due to their proximity and shared embryological development. An understanding of this relationship is vital to understand the reasons for the myriad of symptoms that this region can exhibit.

The embryologic structures from which the head, the face, and the neck originate are segmentally organized during development with the appearance and modification of six paired branchial or pharyngeal arches.[4] These branchial arches contain the cranial nuclei of the trigeminal nerve (ophthalmic; maxillary and mandibular), the facial, the glossopharyngeal, and the laryngeal branch of the vagus nerve as well as the hypoglossal nerve.

The first of these arches, the mandibular arch, consists of a large anterior (ventral) part (the mandibular process of Meckel's cartilage) and a small posterior (dorsal) (maxillary) process. As development progresses, both processes disappear except for two small portions at the posterior (dorsal) ends, which persist. The first brachial arch forms

- the mandible;
- the rudiments of the inner ear bones, the malleus, and incus;
- the anterior malleolar and sphenomandibular ligaments of the TMJ;
- the tensor tympani and the tensor veli palatini of the inner ear;
- the mylohyoid and the anterior belly of the digastric muscle; and
- the trigeminal mandibular nerve.

T e second pharyngeal arch (the hyoid arch) consists of Reichert's cartilage. T is arch is involved in the formation of

- the superior component of the hyoid bone and the lesser cornu bone;
- the stapes muscle;
- the temporal styloid process;
- the stylohyoid ligament;
- the stapedius muscle;
- the stylohyoid muscle;
- the posterior belly of the digastric muscle;
- the muscles of facial expression and mastication;
- the platysma muscle; and
- the glossopharyngeal nerve.

T e third pharyngeal arch is involved in the formation of the greater cornu of the hyoid and its body, the stylopharyngeal muscle, and the sensory apparatus of the posterior one-third of the tongue.

T e fourth pharyngeal arch combines with the sixth arch to form the thyroid, cricoid, and arytenoid cartilages of the larynx. T e muscles derived from this arch are the pharyngeal constrictors (the cricothyroid) and the intrinsic muscles of the larynx. T e pharyngeal constrictors are innervated by the superior laryngeal branch of the vagus nerve. T e intrinsic muscles of the larynx are innervated by the recurrent laryngeal branch of the vagus nerve.

In primitive creatures, and the human fetus, vibrations through the jaw are used as a basis for hearing. At around 8½ weeks, the small bones of the inner ear (the malleus, incus, and stapes) can be seen as distinct entities. T e development of the malleus bone and the tensor tympani are intimately related to that of the lateral pterygoid muscle. Due to this embryological relationship, it is theorized that a spasm of the lateral pterygoid muscle can increase the tension within the tensor tympani (similar to that of a drum skin)[4] resulting in increased sensitivity to pitch and vibration. T eoretically, this increased tension could produce sensorineural tinnitus, or ringing in the ears,[4] a common associated symptom of a TMD, and an injury to the craniovertebral region.

T e diagnosis of TMD, like that of whiplash syndrome, remains controversial.[5] T is is due in part to a paucity of studies regarding the incidence, course, management, and prognosis of claimed TMDs.[6,7] However, reports of TMD appear to be quite common. Although 50–75% of the general population has at least one sign of a TMD, only around one in four people with signs is actually aware of, or reports, any symptoms,[8,9] and only about 5% of people with one or more signs of a TMD will actually seek an intervention.[9–11] TMD tends to affect women more often than men,[12] specifically women over the age of 55.[13] After a technology assessment conference in 1996 about managing TMD, the National Institutes of Health (NIH) concluded that the natural history and etiology of TMD are not well understood and that most TMD symptoms are self-limiting, can recur, and may fluctuate over time.[14] T e most common TMD by far, comprising 90–95% of all TMD cases, is a condition with multiple musculoskeletal facial pain complaints and a variety of jaw impairments, without an identified structural cause.[15]

Due to the complex interplay between the sympathetic and trigeminal nervous systems and an increased understanding of the centralization of pain, TMD is best approached as a cluster of related disorders in the stomatognathic system that have many causes and common symptoms.[16] T ere are likely three etiologic factors of TMD: (1) predisposing factors, (2) precipitating or triggering factors, and (3) perpetuating or sustaining factors[17]:

- Predisposing factors include the structural, neurologic, hormonal, and metabolic features of an individual.
- Precipitating factors generally fall into the following four categories: (1) overt, extrinsic trauma to the head, the neck, or the jaw; (2) repeated low-grade extrinsic trauma, such as nail biting and chewing gum; (3) repeated low-grade intrinsic trauma such as teeth clenching or bruxism (grinding teeth); and (4) stress that passes a certain threshold, which is individual for each patient.
- Perpetuating or contributing factors are those that aid in the continuation of symptoms. T ese can include systemic disease and cervical pathology.

T us, the clinical course of TMD does not reflect a progressive disease but rather a complex disorder that is molded by many interacting factors, such as stress, anxiety, and depression, which serve to maintain the disease.[16] Headaches, orofacial pain, earache, and neck pain are common complaints. A diagnosis of TMD must, therefore, include an examination of all of the following:

- Jaw muscles
- Bone and cartilage joint structures
- Facial structures
- Soft-tissue joint structures, including the articular disk and synovium
- Jaw and joint function
- Cervical and upper thoracic spine function
- Posture and dysfunction
- Systemic disease
- Psychosocial issues

Given the number of potential causes of jaw and face pain, a diagnosis of TMD can rarely be ascribed solely to the TMJ. Examples of appropriate diagnoses for TMD are more likely to include

- rheumatoid arthritis with synovitis, arthralgia, condylar degenerative disease, and open bite deformity;
- chronic pain with a behavioral disorder;
- myofascial pain and impairment; and
- internal disk derangement, with displacement and reduction.

Cl In ICAl PEARl

Most of those who seek medical intervention for TMDs are female. The reason for the higher prevalence of TMD in women, and the overrepresentation of females at orofacial pain clinics remains obscure. One explanation could be that women more readily seek treatment for illness than do men.[18]

Nonsurgical interventions such as counseling, physical therapy, pharmacotherapy, and occlusal splint therapy continue to be the most effective way of managing more than 80% of patients with TMD.[16] Although dentists are the primary professionals involved in the examination and intervention of TMD, physical therapists can play an important role in assisting the dentist in restoring function to the stomatognathic system. However, the procedures in physical therapy intervention are not well described in the literature in this area.

An ATOMY

T e TMJ (Fig. 26-1) is a synovial, compound, modified ovoid bicondylar joint, which is formed between the articular eminence of the temporal bone, the intra-articular disk, and the head of the mandible.

T e TMJ is unique in that, even though the joint is synovial, the articulating surfaces of the bones are covered not by hyaline cartilage but by fibrocartilage.[19,20] Fibrocartilage has the same general properties found in hyaline cartilage but tends to be less distensible, owing to a greater proportion of dense collagen fibers (see Chapter 1). T e development of fibrocartilage over the load-bearing surface of the TMJ indicates that the joint is designed to withstand large and repeated stresses and that this area of the joint surface has a greater capacity to repair itself than would hyaline cartilage.[21]

T e area of load bearing is affected by the congruity of the contacting tooth surfaces (occlusion), head position, and the coordination of muscle function. T e fibrocartilage is at its thinnest at the roof of the fossa, but load bearing here occurs only in the presence of dysfunction.[22]

T e mandible works like a class-three lever (see Chapter 1), with its joint as the fulcrum. Although there is no agreement among the experts concerning force transmission through the joint, there does appear to be agreement that postural impairments of the cervical and upper thoracic spine can produce both pain and impairment of the TMJ.[8]

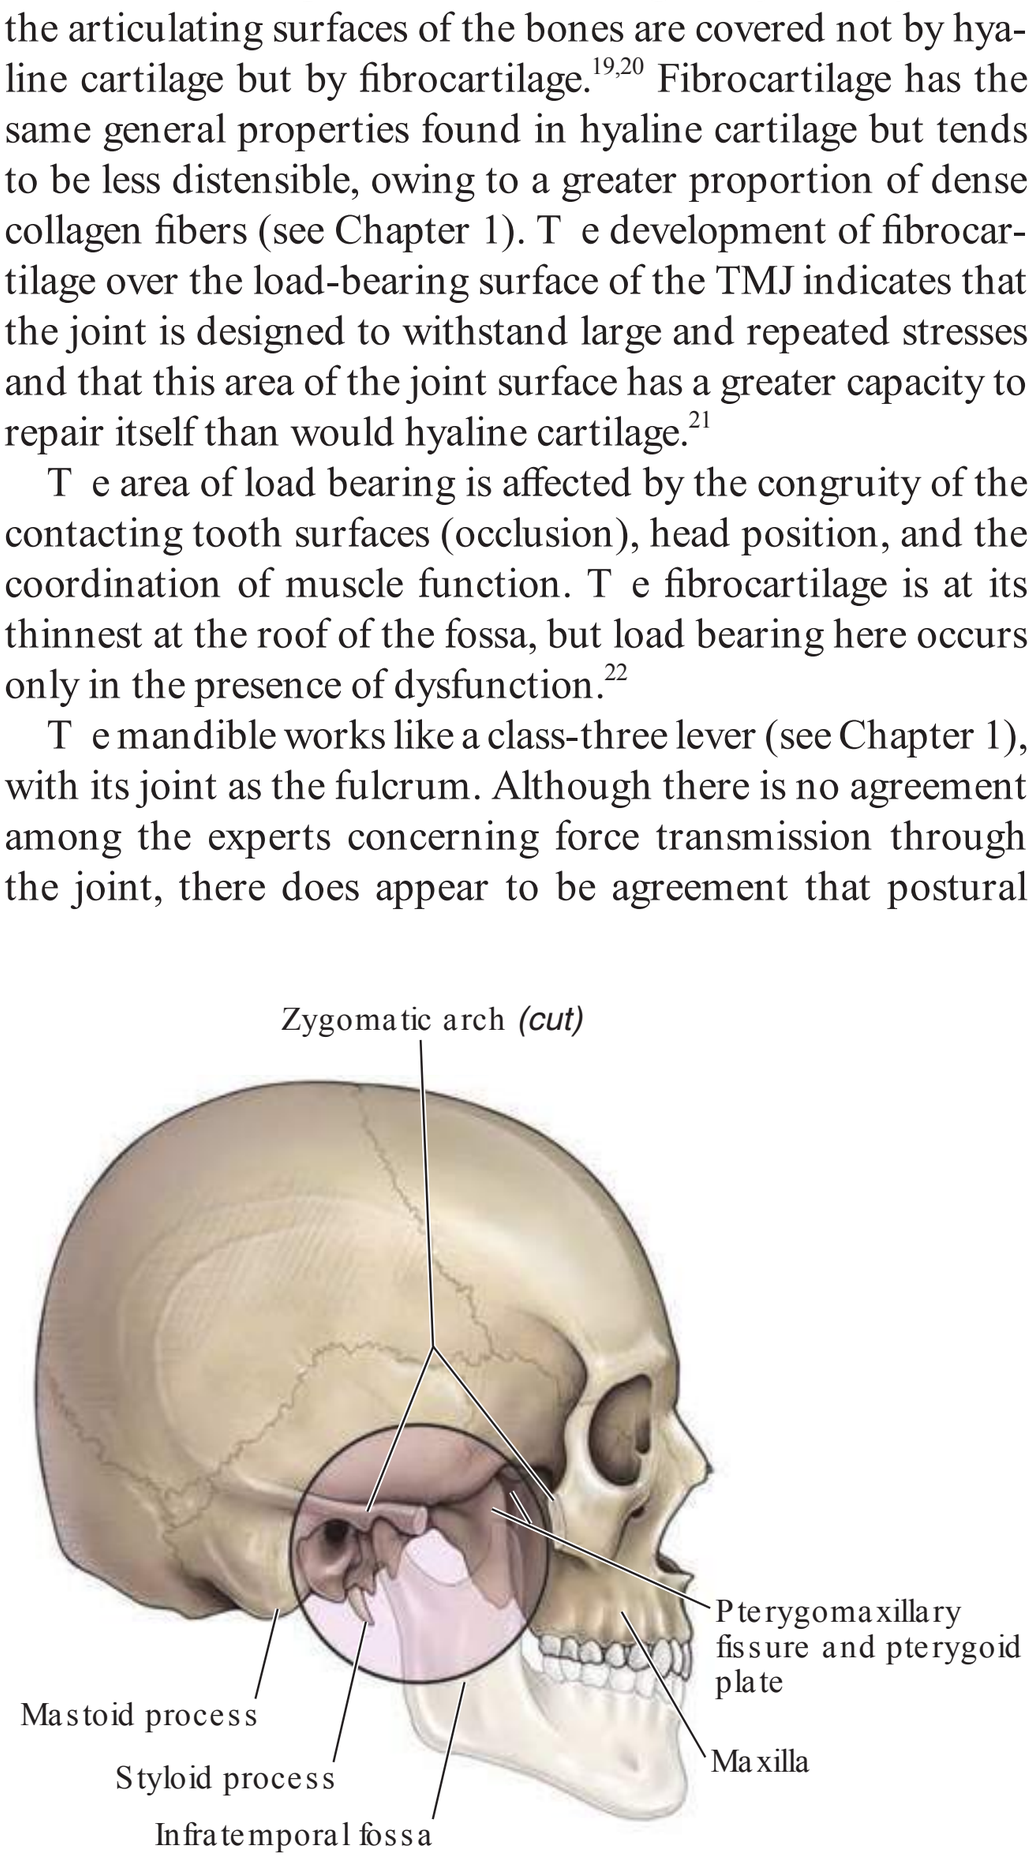

FIGURE 26-1 The temporomandibular joint. (Reproduced, with permission, from Chapter 21. Infratemporal Fossa. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Bony Anatomy

A number of bony components make up the masticatory system: the maxilla and the mandible, which support the teeth, and the temporal bone, which supports the mandible at its articulation with the skull. T e sphenoid bone and the hyoid bone also could be included, because they provide important anatomic and functional links to the TMJ.

Maxilla

T e borders of the maxillae extend superiorly to form the floor of the nasal cavity as well as the floor of each orbit (Fig. 26-1). Inferiorly, the maxillary bones form the palate and the alveolar ridges, which support the teeth. T e maxillae and mandible each contains 16 permanent teeth. T e structure of each tooth reflects its function in mastication.

Sphenoid Bone

T e greater wings of the sphenoid bone form the boundaries of the anterior part of the middle cranial fossa. From these greater wings, the pterygoid laminae serve as the attachments for the medial and lateral pterygoid muscles.

Hyoid Bone

T e U-shaped hyoid bone (Fig. 26-2), also known as the skeleton of the tongue, serves as the attachment for the infrahyoid muscles and for some of the extrinsic tongue muscles. T e hyoid bone is involved with the mandible to provide reciprocal stabilization during swallowing and chewing. T eoretically, due to its muscle attachments, the position of the hyoid bone can be affected by cervical and shoulder positions, as occurs during forward head posture, which changes the length–tension relationships.

Mandible

T e mandible, or jaw (Fig. 26-1), which supports the lower teeth, is the largest and the strongest bone in the face. It is suspended below the maxillae by muscles and ligaments that provide it with both mobility and stability. T e medial surface of the mandible serves as the attachment for the medial pterygoid and the digastric muscles. T e platysma, mentalis, and buccinator gain attachment on its lateral aspect.

Two broad, vertical rami extend upward from the mandible: the condyle and the coronoid process. T e anterior of the two processes, the coronoid, serves as the attachment for the temporalis and masseter muscles.[23] T e condyle process articulates with the temporal bone. T e bony surfaces of the condyle and the articular portion of the temporal bone are made of dense cortical bone. T e articulating surface of the condyle is flattened from front to back with its medial–lateral length twice as long as its anterior–posterior length. T e condyles are generally convex, possessing short bony projections known as medial and lateral poles.[24]

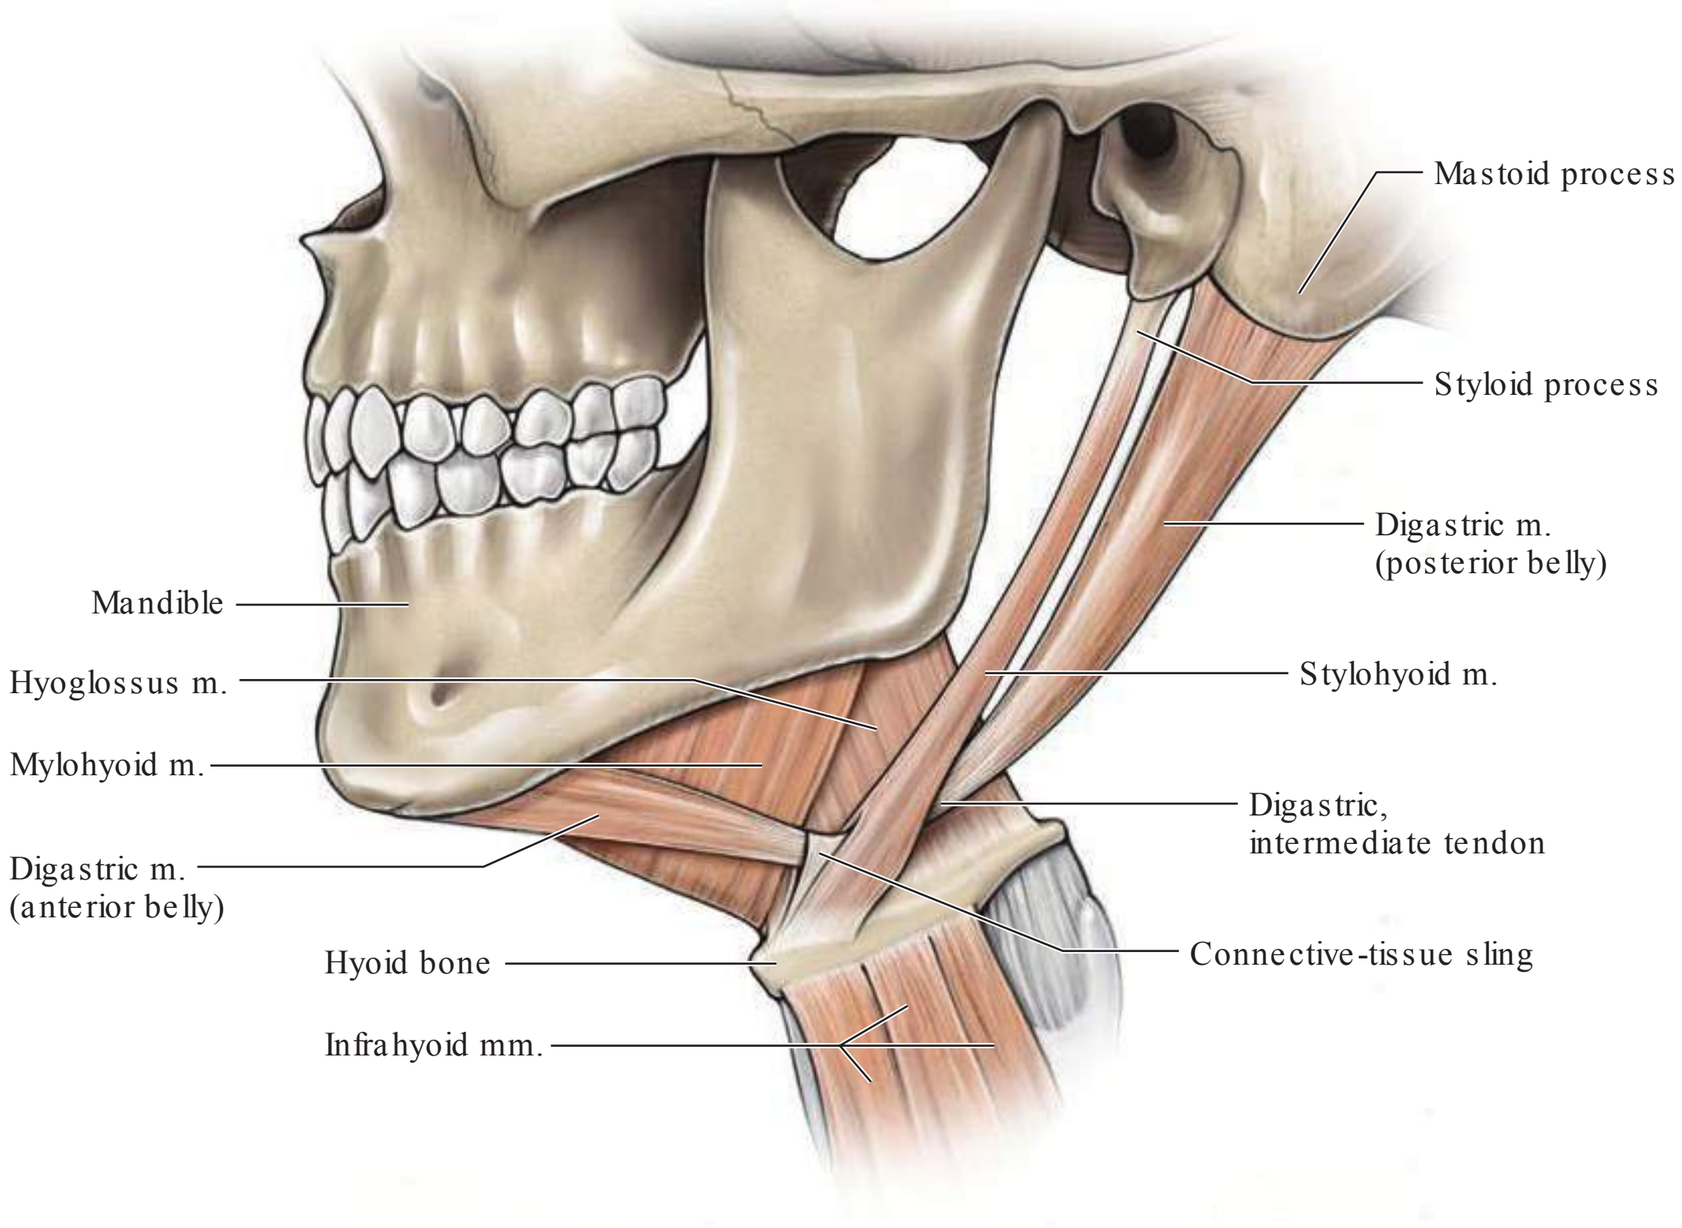

FIGURE 26-2 The hyoid bone and related muscles. (Reproduced, with permission, from Chapter 25. Overview of the Neck. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Temporal Bone

The mandibular fossa of the temporal bone is divided into two surfaces: articular and nonarticular.[24] The articulating surface of the temporal bone is made up of a concave mandibular, or glenoid, fossa and a convex bony prominence called the articular eminence.[25] The articular tubercle, situated anterior to the glenoid fossa, serves as an attachment for the temporomandibular (or lateral) ligament.[23] The nonarticular surface of the fossa consists of a very thin layer of bone and fibrocartilage that occupies much of the superior and posterior walls of the fossa.[24]

Fibrocartilaginous Disk

Located between the articulating surface of the temporal bone and the mandibular condyle is a fibrocartilaginous disk (sometimes inappropriately referred to as "meniscus") (Fig. 26-3). The biconcave shape of the disk is determined by the shape of the condyle and the articulating fossa.[26] Rees[20] has described the fibrocartilaginous disk as having three clearly defined transverse, ellipsoidal zones that are divided into three regions—posterior band, intermediate zone, and anterior band—of which the intermediate zone makes contact with the articular surface of the condyle.

Both the disk and the lateral pterygoid muscle develop from the first branchial arch, and there is very little differentiation among the muscle, the disk, and the joint capsule.[27,28] The fibrocartilaginous disk is tethered by a number of structures:

- Medial and lateral collateral diskal ligaments firmly attach the fibrocartilaginous disk to the medial and lateral poles of the condyle, permitting anterior and posterior rotation of the disk on the condyle during mouth opening and closing.[29,30]
- Posteriorly, the disk is attached by fibroelastic tissue to the posterior mandibular fossa and the back of the mandibular condyle.[29,30]
- Anteriorly, the disk is attached to the upper part of the tendon of the lateral pterygoid muscle (Fig. 26-3).[29,30]

The disk usually is located on top of the condyle in the 12 o'clock to 1 o'clock position on the mandibular head when the jaw is closed.[31] Since the only firm attachment of the disk to the condyle occurs medially and laterally, the disk can move somewhat independently of the condyle.[32]

The disk effectively divides the TMJ into a lower and an upper joint cavity (see Fig. 26-3):

- Lower compartment. This compartment, bordered by the mandibular condyle and the inferior surface of the articular disk, is where, under normal conditions, the osteokinematic spin (rotation) of the condyle occurs.[8]
- Upper compartment. This compartment, bordered by the mandibular fossa and the superior surface of the articular disk, primarily allows only translation of the disk and condyle along the fossa, and onto the articular eminence.[8]

Blood vessels and nerves are found only in the thickened periphery of this disk, especially its posterior attachment; its middle articular portion is avascular and aneural.[33]

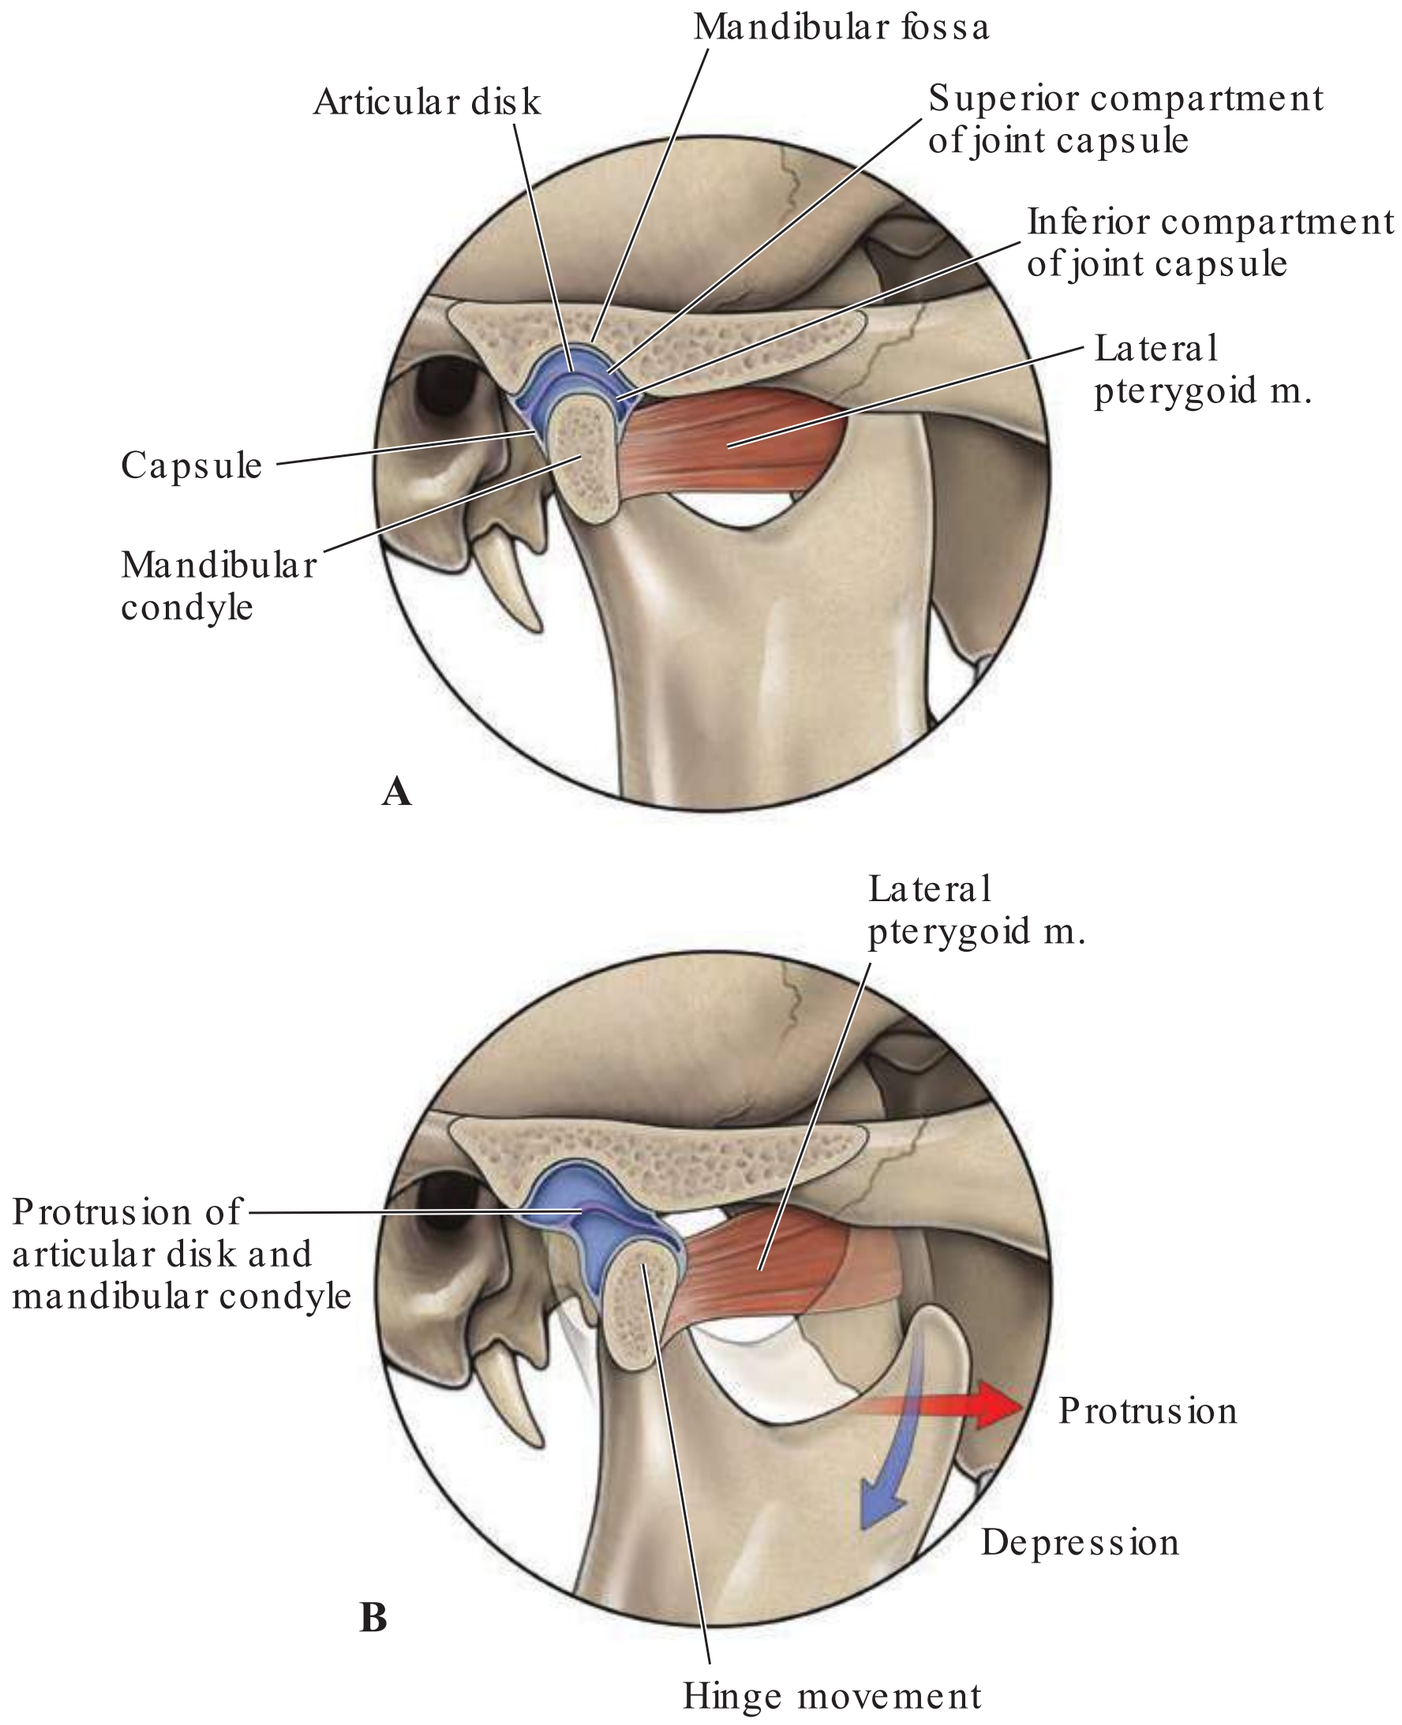

FIGURE 26-3 The TMJ disk and the pterygoid. (Reproduced, with permission, from Chapter 21. Infratemporal Fossa. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Supporting Structures

The supporting structures of the TMJ consist of periarticular connective tissue (ligament, tendon, capsule, and fascia). As its name implies, the periarticular connective tissue serves to keep the joints together and to limit the ranges of motion at the joint. For example, the ligaments of the TMJ protect and support the joint structures and act as passive restraints to joint movement. The synovial cavities are surrounded by loose connective tissue rather than by ligaments.

The intercapsular structures are located posteriorly to the condyle. Anterior to the joint are the muscles of the medial and lateral pterygoid (see next section). There are no well-defined anterior or posterior ligaments between the mandibular condyle and the temporal bone. However, two strong ligaments help to provide joint stability:

1. Joint capsule or capsular ligament. This structure, which surrounds the entire joint, is thought to provide proprioceptive feedback regarding the joint position and movement.[34,35]
2. Temporomandibular (or lateral) ligament. The capsule of the TMJ is reinforced laterally by an outer oblique portion and an inner horizontal portion of the temporomandibular ligament, which function as a suspensory mechanism for the mandible during moderate opening movements. The ligament also functions to resist rotation and posterior displacement of the mandible.

Two other ligaments assist with joint stability:

1. Stylomandibular ligament. The stylomandibular ligament is a specialized band that splits away from the superficial lamina of the deep cervical fascia to run deep to both pterygoid muscles.[25] This ligament becomes taut and acts as a guiding mechanism for the mandible, keeping the condyle, disk, and temporal bone firmly opposed.
2. Sphenomandibular ligament. The sphenomandibular ligament is a thin band that runs from the spine of the sphenoid bone to a small bony prominence on the medial surface of the ramus of the mandible, called the lingula. This ligament acts to check the angle of the mandible from sliding

as far forward as the condyles during the translatory cycle and serves as a suspensory ligament of the mandible during wide opening.[25] It is this ligament that hurts with any prolonged jaw opening, such as that which occurs at the dentist.

Cl In ICAl PEARl

Pinto's ligament[36] is a vestige of Meckel's cartilage, an embryological tissue. It arises from the neck of the malleus of the inner ear and runs in a medial-superior direction to insert into the posterior aspect of the TMJ capsule and disk. While the role of this ligament in mandibular mechanics is thought to be negligible, its relationship to the middle ear and the TMJ could be a basis for the middle ear symptoms, which are often present with TMD. Stack and Funt[37] postulated that auditory symptoms of fullness and pressure in the middle ear might be present as a result of direct transmission of TMJ capsular tension to the ossicles of the middle ear through this ligament.

Muscles

T e muscles of mastication are the key muscles when discussing TMD. T ree of these muscles, the masseter, the medial pterygoid, and the temporalis (Fig. 26-4), function to raise the mandible during mouth closing. T e lateral pterygoid and digastric muscles work together to depress the mandible during mouth opening.

Although these muscles work most efficiently in groups, an understanding of the specific anatomy and action(s) of the individual muscles is necessary for an appreciation of their coordinated function during masticatory activity (Tables 26-1 and 26-2).

Temporalis

T e temporalis muscle (Fig. 26-4) has its origin from the floor of the temporal fossa and the temporal fascia. T e muscle travels inferiorly and anteriorly to insert on the anterior border of the coronoid process and the anterior border of the ramus of the mandible. T e temporalis muscle is innervated by a branch of the mandibular division of the trigeminal nerve. In addition to assisting with mouth closing and side-to-side grinding of the teeth, the temporalis muscle provides a good deal of stability to the joint.

The Masseter

T e masseter (Fig. 26-4) is a two-layered quadrilateral-shaped muscle. T e superficial portion arises from the anterior two-thirds of the lower border of the zygomatic arch. T e deep portion arises from the medial surface of the zygomatic arch. Both sets of fibers blend anteriorly and form a raphe with the medial pterygoid.[25] T e masseter inserts on the lateral surface of the coronoid process of the mandible, the upper half of the ramus and angle of the mandible. T e masseter muscle is innervated by a branch of the mandibular division of the trigeminal nerve. T e major function of the masseter is to elevate the mandible, thereby occluding the teeth during mastication.

The Medial Pterygoid

T e medial pterygoid muscle is a thick quadrilateral muscle, with a deep origin situated on the medial aspect of the mandibular ramus (Fig. 26-4). T e muscle travels posteriorly to insert on the inferior and posterior aspects of the medial subsurface of the ramus and angle of the mandible. T e medial pterygoid muscle is innervated by a branch of the

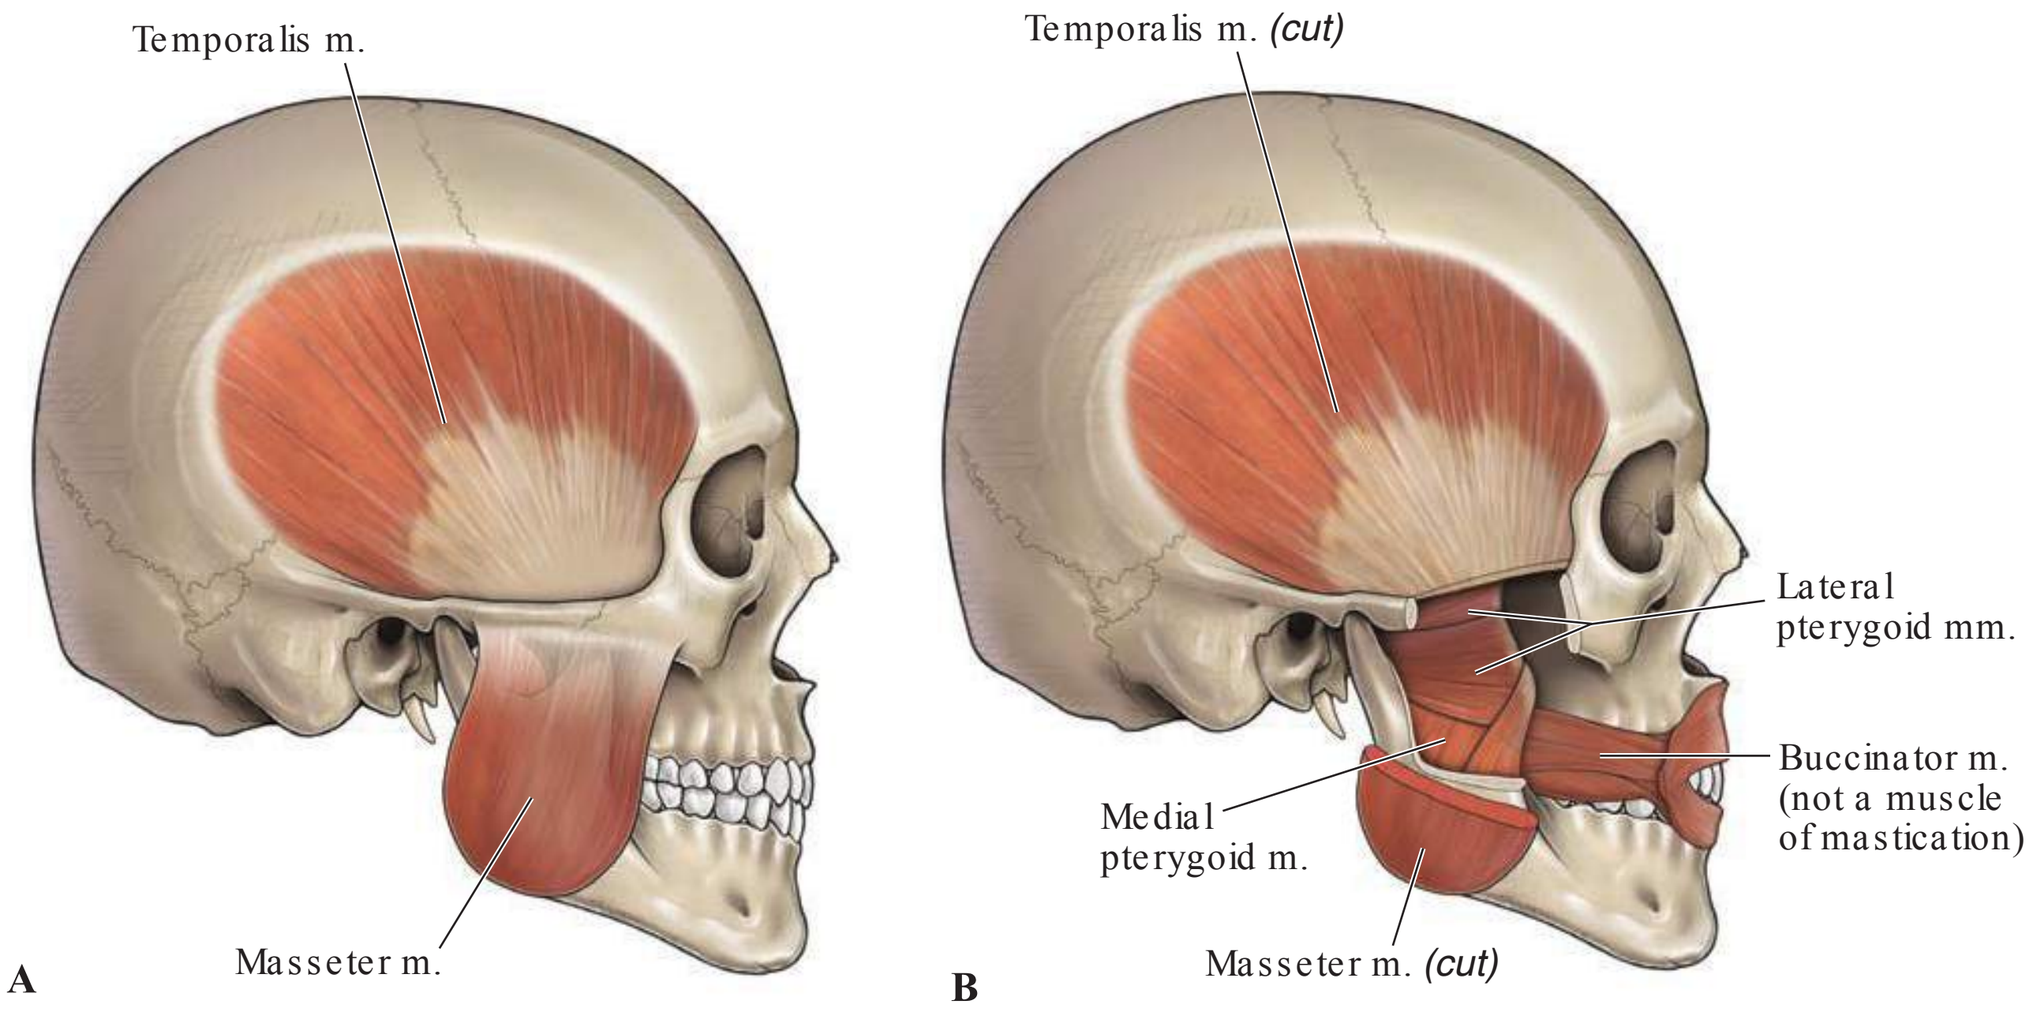

FIGURE 26-4 Lateral view of TMJ. (Reproduced, with permission, from Chapter 21. Infratemporal Fossa. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

TABLE 26-1 Muscles of the Temporomandibular Joint

Muscle	Proximal	Distal	Innervation
Medial pterygoid	Medial surface of lateral pterygoid plate and tuberosity of maxilla	Medial surface of mandible close to angle	Mandibular division of trigeminal nerve
Lateral pterygoid	Greater wing of sphenoid and lateral pterygoid plate	Neck of mandible and articular cartilage	Mandibular division of trigeminal nerve
Temporalis	Temporal cranial fossa	By way of a tendon into medial surface, apex, and anterior and posterior borders of mandibular ramus	Anterior and posterior deep temporal nerves, which branch from anterior division of mandibular branch of trigeminal nerve
Masseter	Superficial portion: from anterior two-thirds of lower border of zygomatic arch; deep portion from medial surface of zygomatic arch	Lateral surfaces of coronoid process of mandible, upper half of ramus, and angle of mandible	Masseteric nerve from anterior trunk of mandibular division of trigeminal nerve
Mylohyoid	Medial surface of mandible	Body of hyoid bone	Mylohyoid branch of trigeminal nerve and mandibular division
Geniohyoid	Mental spine of mandible	Body of hyoid bone	Anterior (ventral) ramus of C1 via hypoglossal nerve
Stylohyoid	Styloid process of temporal bone	Body of hyoid bone	Facial nerve
Anterior and posterior digastric	Internal surface of mandible and mastoid process of temporal bone	By intermediate tendon to hyoid bone	Anterior: mandibular division of trigeminal nerve; posterior: facial nerve
Sternohyoid	Manubrium and medial end of clavicle	Body of hyoid bone	Ansa cervicalis
Omohyoid	Superior angle of scapula	Inferior body of hyoid bone	Ansa cervicalis
Sternothyroid	Posterior surface of manubrium	Thyroid cartilage	Ansa cervicalis
Thyrohyoid	Thyroid cartilage	Inferior body and greater horn of hyoid bone	C1 via hypoglossal nerve

mandibular division of the trigeminal nerve. Working bilaterally, and in association with the masseter and temporalis muscles, the medial pterygoids assist in mouth closing. Individually, the medial pterygoid muscle is capable of deviating the mandible toward the opposite side. The medial pterygoid muscle also assists the lateral pterygoid and anterior fibers of the temporalis muscle to produce protrusion of the mandible.

The Lateral Pterygoid

Two divisions of the lateral pterygoid muscles are recognized, each of which is functionally and anatomically separate (Figs. 26-3 and 26-4). The superior head arises from the infratemporal surface of the greater wing of the sphenoid. The inferior head arises from the lateral surface of the lateral pterygoid plate. Despite several investigations,[38–40] no consensus has been reached regarding the insertion of the lateral pterygoid muscle. However, the most commonly described insertion is at the anterior aspect of the neck of the mandibular condyle and capsule of the TMJ. The lateral pterygoid muscle is innervated by a branch of the mandibular division of the trigeminal nerve.

The superior head of the lateral pterygoid is involved mainly with chewing and functions to rotate the disk anteriorly on the condyle during the closing movement.[41,42] It has also been suggested that in normal function of the craniomandibular complex, the superior lateral pterygoid plays an important role in stabilizing and controlling the movements of the disk.[43]

The inferior head of the lateral pterygoid muscle exerts an anterior, lateral, and inferior pull on the mandible, thereby opening the jaw, protruding the mandible, and deviating the mandible to the opposite side.

Infrahyoid or "Strap" Muscles

The infrahyoid muscles comprise the sternohyoid, omohyoid, sternothyroid, and thyrohyoid muscles (Fig. 26-5).

Sternohyoid

The sternohyoid muscle is a strap-like muscle that functions to depress the hyoid and assist in speech and mastication.

Omohyoid

The omohyoid muscle, situated lateral to the sternohyoid, consists of two bellies and functions to depress the hyoid. In addition, the muscle has been speculated to tense the inferior aspect of the deep cervical fascia in prolonged inspiratory

TABLE 26-2	Actions of the Temporomandibular Joint Muscles
Action	**Muscles Acting**
Opening of mouth	Lateral pterygoid Mylohyoid Geniohyoid Digastric
Closing of mouth	Masseter Temporalis Medial pterygoid
Protrusion of mandible	Lateral pterygoid Medial pterygoid Masseter Mylohyoid Geniohyoid Digastric Stylohyoid Temporalis (anterior fibers)
Retraction of mandible	Temporalis (posterior fibers) Masseter Digastric Stylohyoid Mylohyoid Geniohyoid
Lateral deviation of mandible	Lateral pterygoid (ipsilateral muscle) Medial pterygoid (contralateral muscle) Temporalis Masseter

efforts, thereby releasing tension on the apices of the lungs and on the internal jugular vein, which are attached to this fascial layer.[25]

Sternothyroid and Thyrohyoid

The sternothyroid and thyrohyoid muscles (see Fig. 26-5) are located deep to the sternohyoid muscle. The sternothyroid muscle is involved in drawing the larynx downward, whereas the thyrohyoid depresses the hyoid and elevates the larynx.

These infrahyoid muscles are innervated by fibers from the upper cervical nerves. The nerves to the lower part of these muscles are given off from a loop, the ansa cervicalis (cervical loop) (see Chapter 3).

Suprahyoid Muscles

The suprahyoid muscles (Fig. 26-2), working with the infrahyoid muscles, play a major role in coordinating mandibular function, by providing a firm base on which the tongue and mandible can be moved.

Geniohyoid

The geniohyoid muscle is a narrow muscle situated under the mylohyoid muscle. The muscle functions to elevate the hyoid bone.

Digastric

As its name suggests, the digastric muscle consists of two bellies. The posterior belly arises from the mastoid notch of the temporal bone while the anterior belly arises from the digastric fossa of the mandible. The posterior belly is innervated by a branch of the facial nerve. The anterior belly is innervated by the inferior alveolar branch of the trigeminal nerve. The two bellies of the digastric muscle are joined by a rounded tendon that attaches to the body and greater cornu of the hyoid bone through a fibrous loop or sling.[25]

Bilaterally, the two bellies of the digastric muscle assist in forced mouth opening by stabilizing the hyoid. The posterior bellies are especially active during coughing and swallowing.[25]

Clinical Pearl

The muscles of the TMJ, working in combinations, are involved as follows:

- Mouth opening—bilateral action of the lateral pterygoid and digastric muscles.
- Mouth closing—bilateral action of the temporalis, masseter, and medial pterygoid muscles.
- Lateral deviation—action of the ipsilateral masseter, and contralateral medial and lateral pterygoid muscles.
- Protrusion—bilateral action of the lateral pterygoid, medial pterygoid, and anterior fibers of the temporalis muscles.
- Retrusion—bilateral action of the posterior fibers of the temporalis muscle, the digastric, stylohyoid, geniohyoid, and mylohyoid muscles.

Mylohyoid

This flat, triangular muscle is functionally a muscle of the tongue, stabilizing or elevating the tongue while swallowing and elevating the floor of the mouth in the first stage of deglutition.[25]

Stylohyoid

The stylohyoid muscle elevates the hyoid and base of the tongue and has an undetermined role in speech, mastication, and swallowing.

Nerve Supply

The TMJ is primarily supplied by three nerves that are part of the mandibular division of the fifth cranial (trigeminal) nerve (Fig. 26-6) (Box 26-1). Portions of the middle ear ossicles, middle ear musculature, and muscles of mastication all originate from the first branchial arch and are innervated by this nerve. Therefore, in a patient with altered bite mechanics, spasm of the muscles of mastication caused by a displaced condyle may cause neuromuscular dysfunction of all the muscles innervated by the trigeminal nerve, including the tensor palatini.[44]

There is considerable clinical interest in the interactions between the cervical and craniofacial regions. This interest stems from a number of reports concerning patients who have pain in the cervical and craniofacial areas simultaneously.[32,45–48]

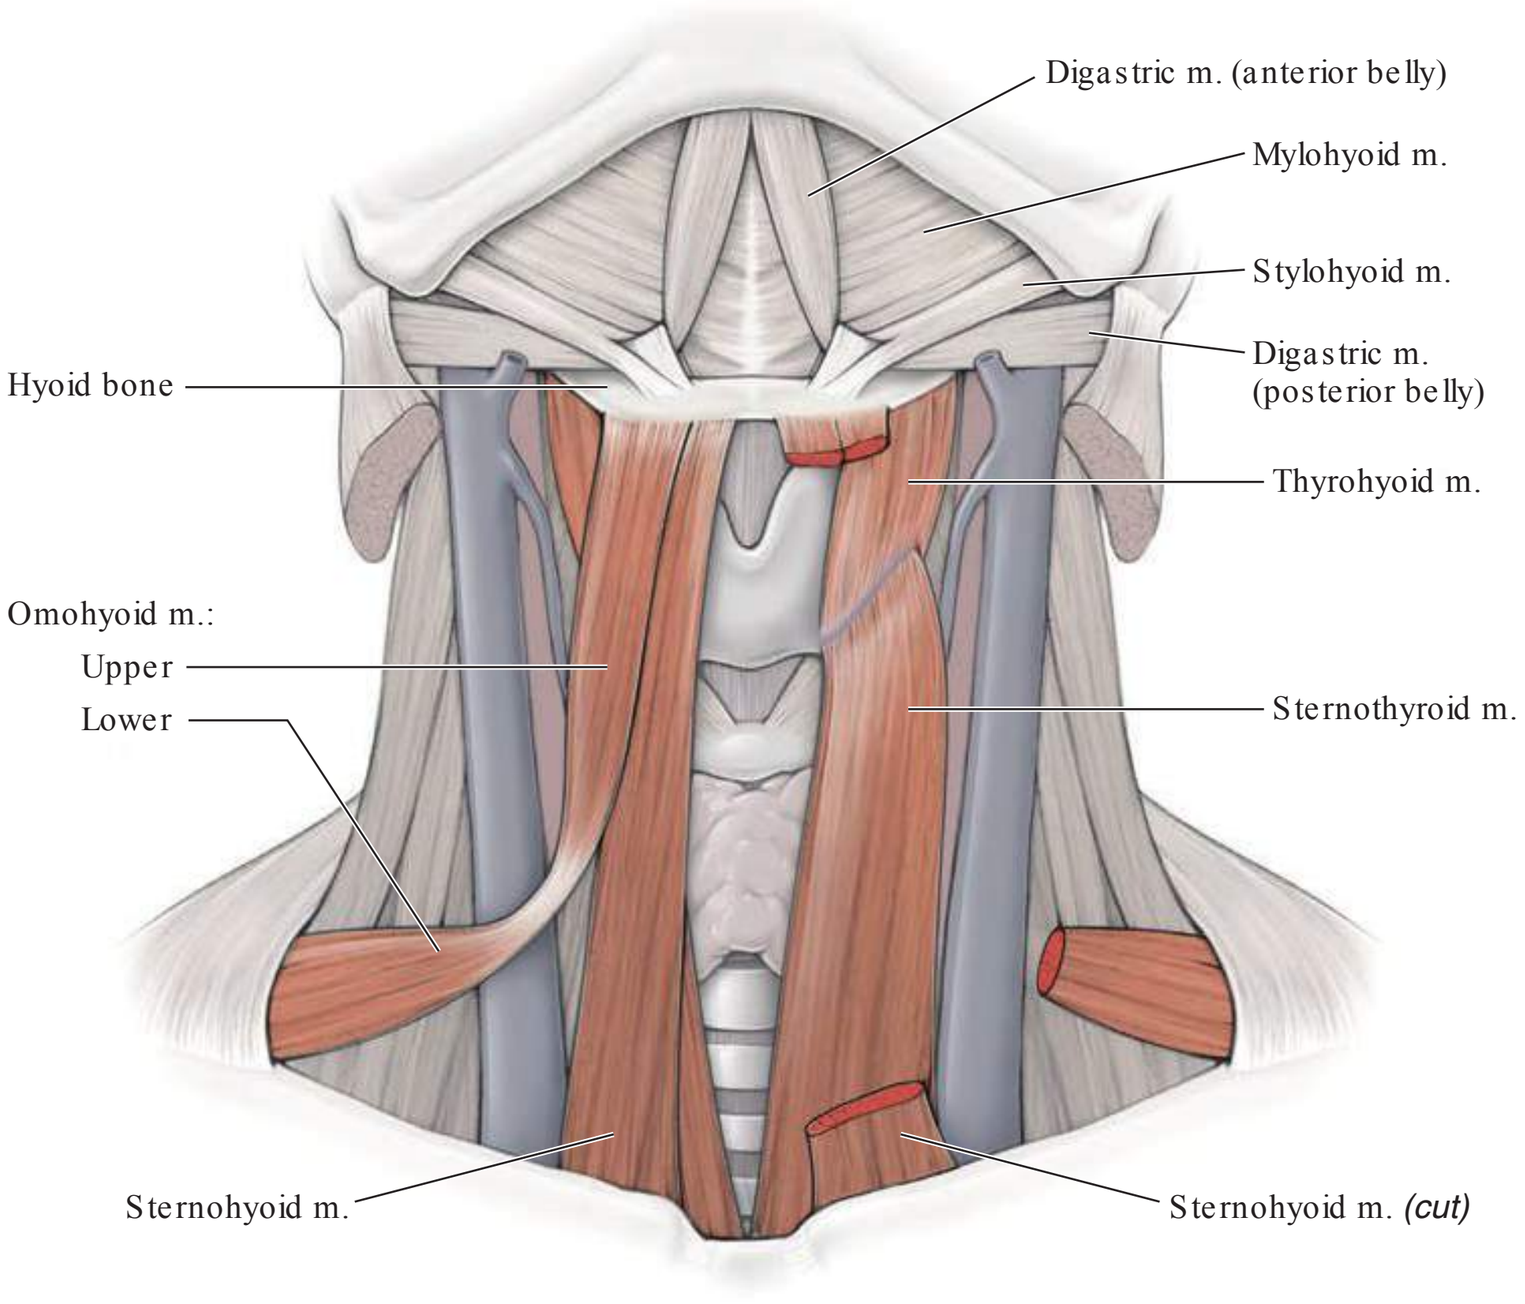

FIGURE 26-5 The infrahyoid muscles. (Reproduced, with permission, from Chapter 25. Overview of the Neck. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

In the suboccipital region, a series of dense neural connections, called the trigeminocervical complex, exists among trigeminal, facial, glossopharyngeal, and vagus nerves, with those of the upper C1–4 cervical spinal nerves (Fig. 26-7).[17] Postural abnormalities resulting from various acute or chronic etiologies that produce suboccipital compression may, therefore, be responsible for craniofacial pain anywhere in the head, in addition to symptoms of dizziness or nystagmus.[7,17,49]

TMJ-related headaches usually include pain near the TMJ and ear, ear fullness, temporal headaches, and facial pain.[50] The dizziness associated with TMD tends to be of the nonvertiginous variety, with the patient complaining of unsteadiness, giddiness, or lightheadedness.[51] Although the exact mechanism is unclear, postural influences, alteration in the position of the jaw by the malocclusion, and the subsequent mismatching between the cervical muscles might be the cause.[51]

BIOMECHANICS

The movements that occur at the TMJ are extremely complex. The TMJ has three degrees of freedom, with each of the degrees of freedom being associated with a separate axis of rotation.[52] Two primary arthrokinematic movements (rotation and anterior translation) occur at this joint around three planes: sagittal, horizontal, and frontal.

Rotation occurs from the beginning to the midrange of movement. In addition to the rotational motions during mouth opening and closing and lateral deviations, movements at the TMJ involve arthrokinematic rolls and slides. Gliding, translation, or sliding movements occur in the upper cavity, whereas rotation or hinged movement occurs in the lower cavity. The motions of protrusion and retrusion are planar glides. Thus,

- mouth opening, contralateral deviation, and protrusion all involve an anterior osteokinematic rotation of the mandible and an anterior, inferior, and lateral glide of the mandibular head and disk;
- mouth closing, ipsilateral deviation, and retrusion all involve a posterior osteokinematic rotation of the mandible and an anterior, inferior, and lateral glide of the mandibular head and disk.

Occlusal Position

Occlusal positions are functional positions of the TMJ. The occlusal position is defined as the point at which contact between some or all of the teeth occurs. Under normal circumstances, the upper molars rest directly on the lower molars and the upper incisors slightly override the lower incisors. The ideal position provides mutual protection of

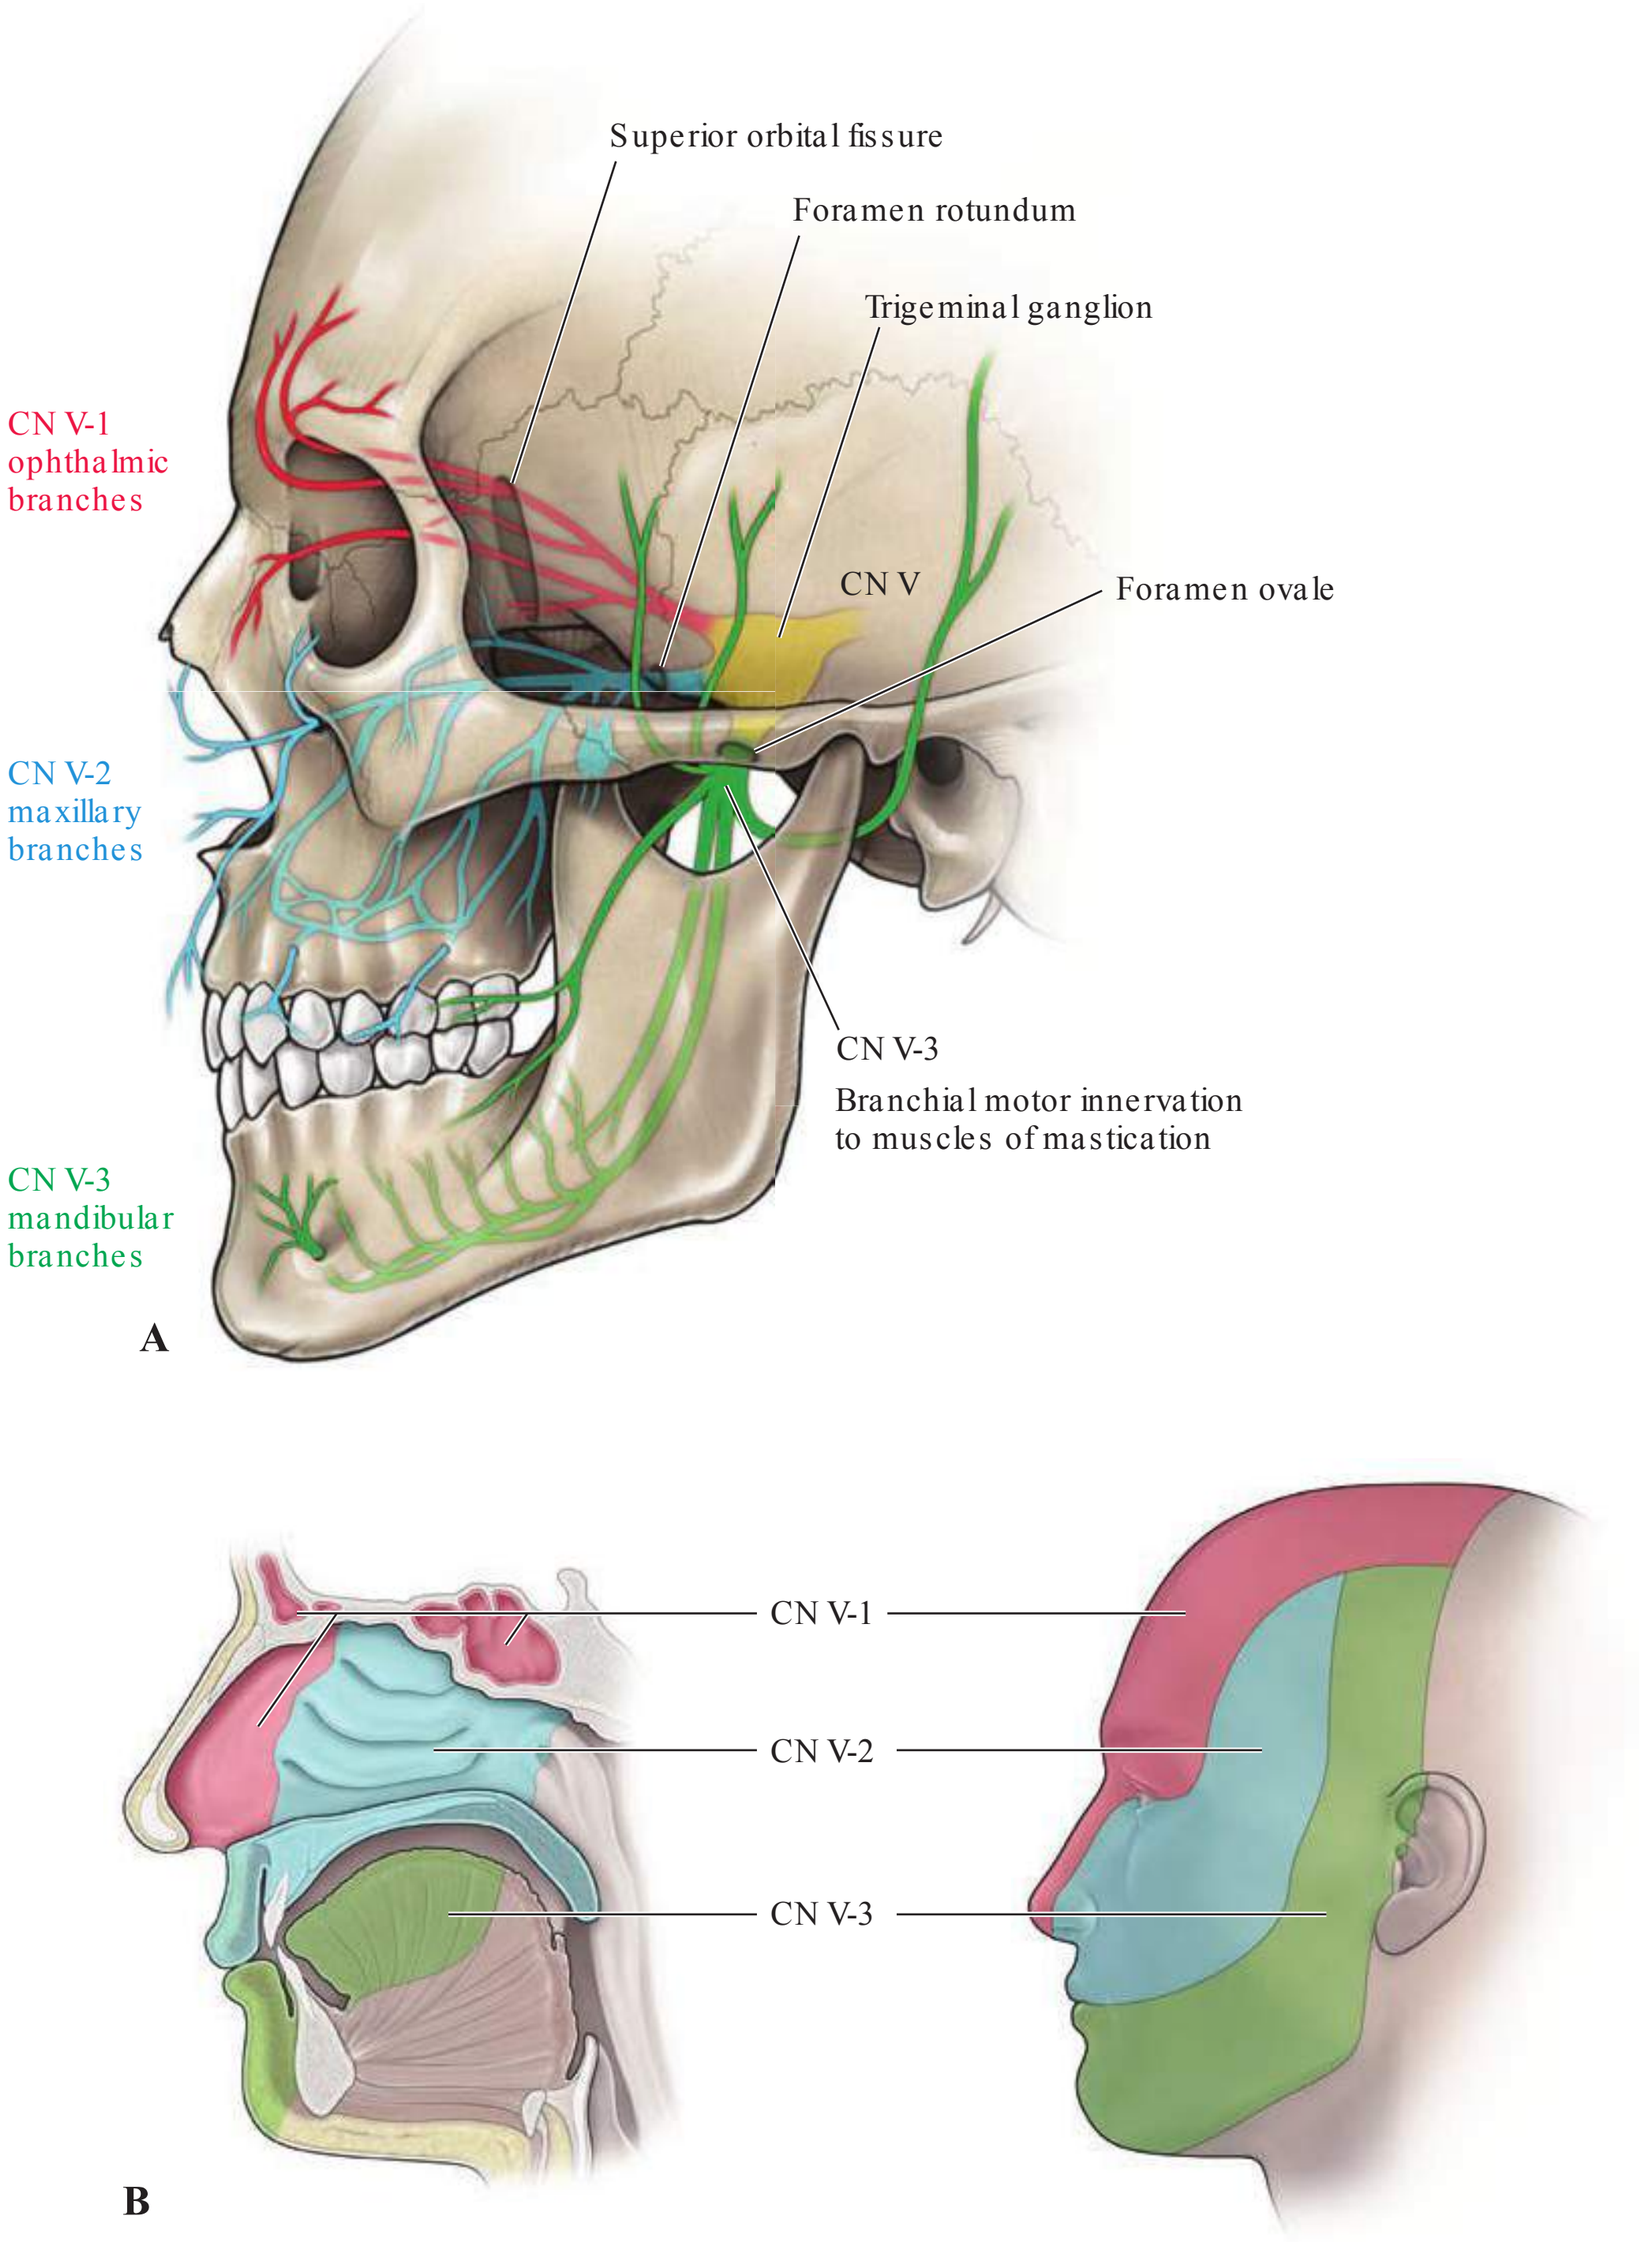

FIGURE 26-6 The trigeminal nerve. (Reproduced, with permission, from Chapter 17. Cranial Nerves. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

the anterior and posterior teeth, comfortable and painless mandibular function, and stability.[17]

- The median occlusal position corresponds to the position in which all of the teeth are fully interdigitated[19] and is considered the start position for all mandibular motions. The median occlusal position is dependent on the presence, shape, and position of the teeth. Protrusion of the upper or lower incisors, failure of the upper incisors to overlap with the lower incisors, absent or abnormally shaped teeth, and back teeth that do not meet are all causes of malocclusion.
- The centric position is considered to be the position that implies the most retruded, unstrained position of the mandible from which lateral movements are possible, and the components of the oral apparatus are the most balanced.[53] Ideally, the centric position should coincide with the median occlusal position.[53] It is worth remembering that malocclusion is probably very common in the general nonsymptomatic patient and may or may not be relevant to the presenting symptoms.[54] Rather than being a primary etiologic factor in TMD, malocclusion is likely to have a secondary or contributory role.[17,55]

Box 26-1 Characteristics of the Trigeminal Nerve

Motor Nucleus

The anterolateral upper pons.

Sensory Nucleus

There are two nuclei: (1) the chief sensory nucleus in the posterior (dorsal)-lateral pons and (2) the mesencephalic nucleus, which extends from the chief sensory nucleus upward through the pons to the midbrain.

Spinal Nucleus

The spinal tract consists of small- and medium-sized myelinated nerve fibers and runs caudally to reach the upper cervical segments of the spinal cord. The lowest nerve fibers in the tract mix with the spinal fibers in the tract of Lissauer.

Nerves

- Mandibular
- Ophthalmic
- Maxillary

Termination

- Muscles of mastication, both pterygoids, tensor veli palatini, tensor tympani, mylohyoid, and anterior belly of digastric.
- Skin of vertex, temporal area, forehead, and face; mucosa of sinuses, nose, pharynx, anterior two-thirds of tongue, and oral cavity.
- Lacrimal, parotid, and lingual glands; dura of anterior and middle cranial fossae.
- External aspect of tympanic membrane and external auditory meatus, TMJ, and teeth.
- Dilator pupillae and probably proprioceptors of extraocular muscles.
- Sensation from upper three or four cervical levels.

TABLE 26-3 Arthrokinematic Steps of the Temporomandibular Joint

Step	Movement
Rest position	Joint is in an open-packed position
Rotation	There is a mid-opening Condylar joint surfaces glide forward, inferior joint surface of disk has a relative posterior glide, upper lateral pterygoid relaxes, inferior pterygoid contracts, and posterior connective tissue is in a functional state of rest
Functional opening	Disk and condyle experience a short anterior translatory glide; superior and inferior heads of lateral pterygoid contract to guide disk and condyle forward Posterior connective tissue is in a functional tightening
Translation	There is full opening Disk and condyle glide anteriorly and caudally Superior and inferior heads of lateral pterygoid contract to guide disk and condyle fully forward Posterior connective tissues tighten
Closure	Surface of condyle joint glides posteriorly, and disk glides relative to anterior surface Superior head of lateral pterygoid contracts and inferior head relaxes Posterior connective tissue returns to its functional length

Data from Rocabado M. Arthrokinematics of the temporomandibular joint. In: Gelb H, ed. Clinical Management of Head, Neck and TMJ Pain and Dysfunction. Philadelphia, PA: WB Saunders; 1985.

Mouth Opening

Mouth opening occurs in a series of steps (Table 26-3). In the erect position, the condyles begin to rotate anteriorly and translate inferiorly and laterally during the first 25 degrees of opening as the jaw opens. The upper head of the lateral pterygoid muscle and the anterior head of the digastric muscle draw the disk anteriorly and prepare for condylar rotation during movement.[32] This is initial condylar rotation occurs as the mandibular elevators (masseter, temporalis, and medial pterygoid muscles) gradually relax and lengthen, allowing gravity to depress the mandible (see Fig. 26-8).[32] The directions of the fibers of the lateral and medial temporomandibular ligaments also keep the condyle from moving posteriorly. The fibrous capsule and parts of the temporomandibular ligament limit excessive lateral movement of the condyle. The rotation occurs through the two condylar heads between the articular disk and the condyle. As the mandible moves forward on opening, the disks move medially and posteriorly until the collateral ligaments, and the lateral pterygoid stop their movement. During the last 15 degrees of opening, the rotation ceases due to tightening of the collateral ligaments, and is replaced by an anterior translation of the condyles (see Fig. 26-8).[56] During this translation, the condyle and disk move together. The anterior translation, which is produced mainly by muscle contraction, serves to prevent mandibular encroachment of the anterior neck structures. Opening is also assisted by the other suprahyoid muscles.[32] In extremely wide opening, such as that occurs with yawning, the functional joint contact is on the distal aspect of the condyle, and the anterior lateral aspect of the condyle contacts the posterior part of the masseter muscle. In this position, the soft-tissue structures are in a position of stretch, making them more prone to dysfunction.[57]

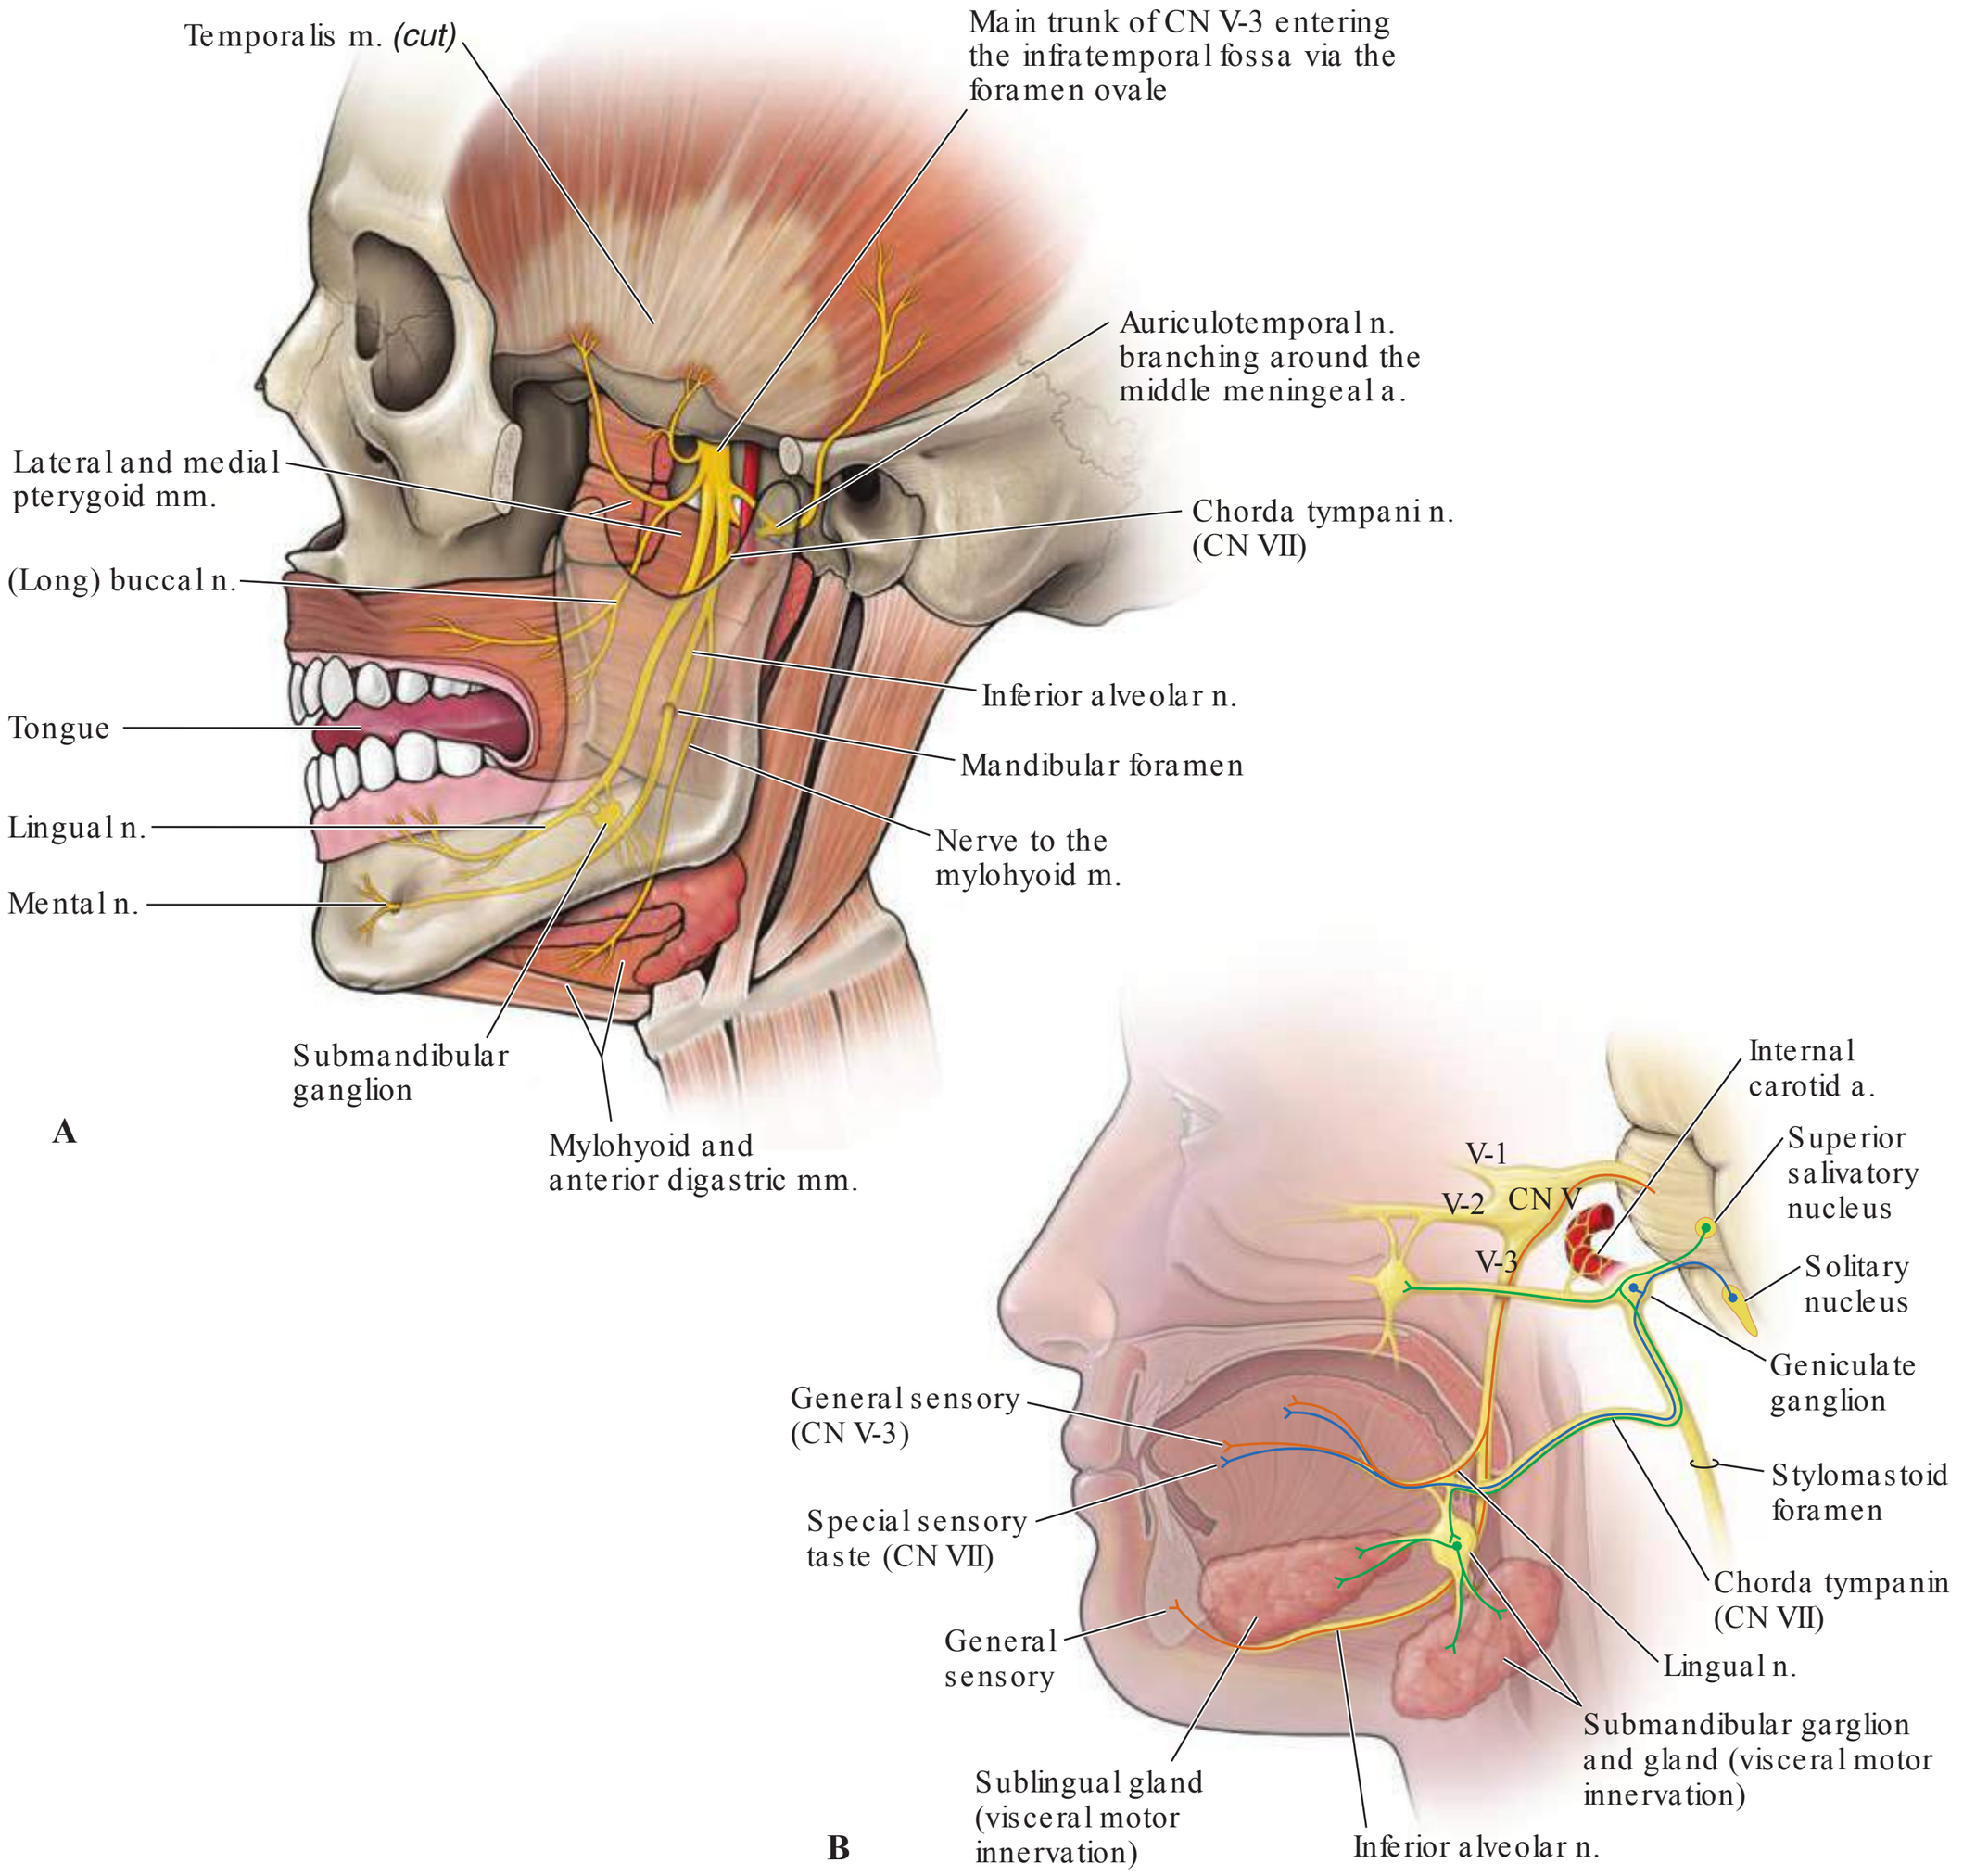

FIGURE 26-7 Neurology of the TMJ. (Reproduced, with permission, from Chapter 21. Infratemporal Fossa. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Mouth Closing

Closing of the mouth involves a reversal of the movements described for mouth opening. The condyles translate posteriorly as a result of an interaction between the retracting portions of the masseter and temporalis muscle and the retracting portions of the mandibular depressors (see Fig. 26-8).[52] As the condyles translate posteriorly and glide medially, they hinge on the disks. The disks then glide posteriorly and superiorly on the temporal bone along with the condyles (as a result of the actions of the masseter, medial pterygoid, and temporalis muscles).[42] When the jaws are closed to maximal occlusal contact, the condyles contact the disks, and the disks contact the posterior slopes of the articular tubercles and the glenoid fossae.

Protrusion

Protrusion is a forward movement of the mandible that occurs at the superior joint compartments, which consists of the disk and condyle moving downward, forward, and laterally. The muscles responsible for protrusion are the anterior fibers of the temporalis and the medial and lateral pterygoid muscles.

Retrusion

Retrusion is a backward movement of the mandible, produced by the posterior fibers of the temporalis and assisted by the suprahyoid muscles. The retrusive range is limited by the extensibility of the temporomandibular ligaments.[58]

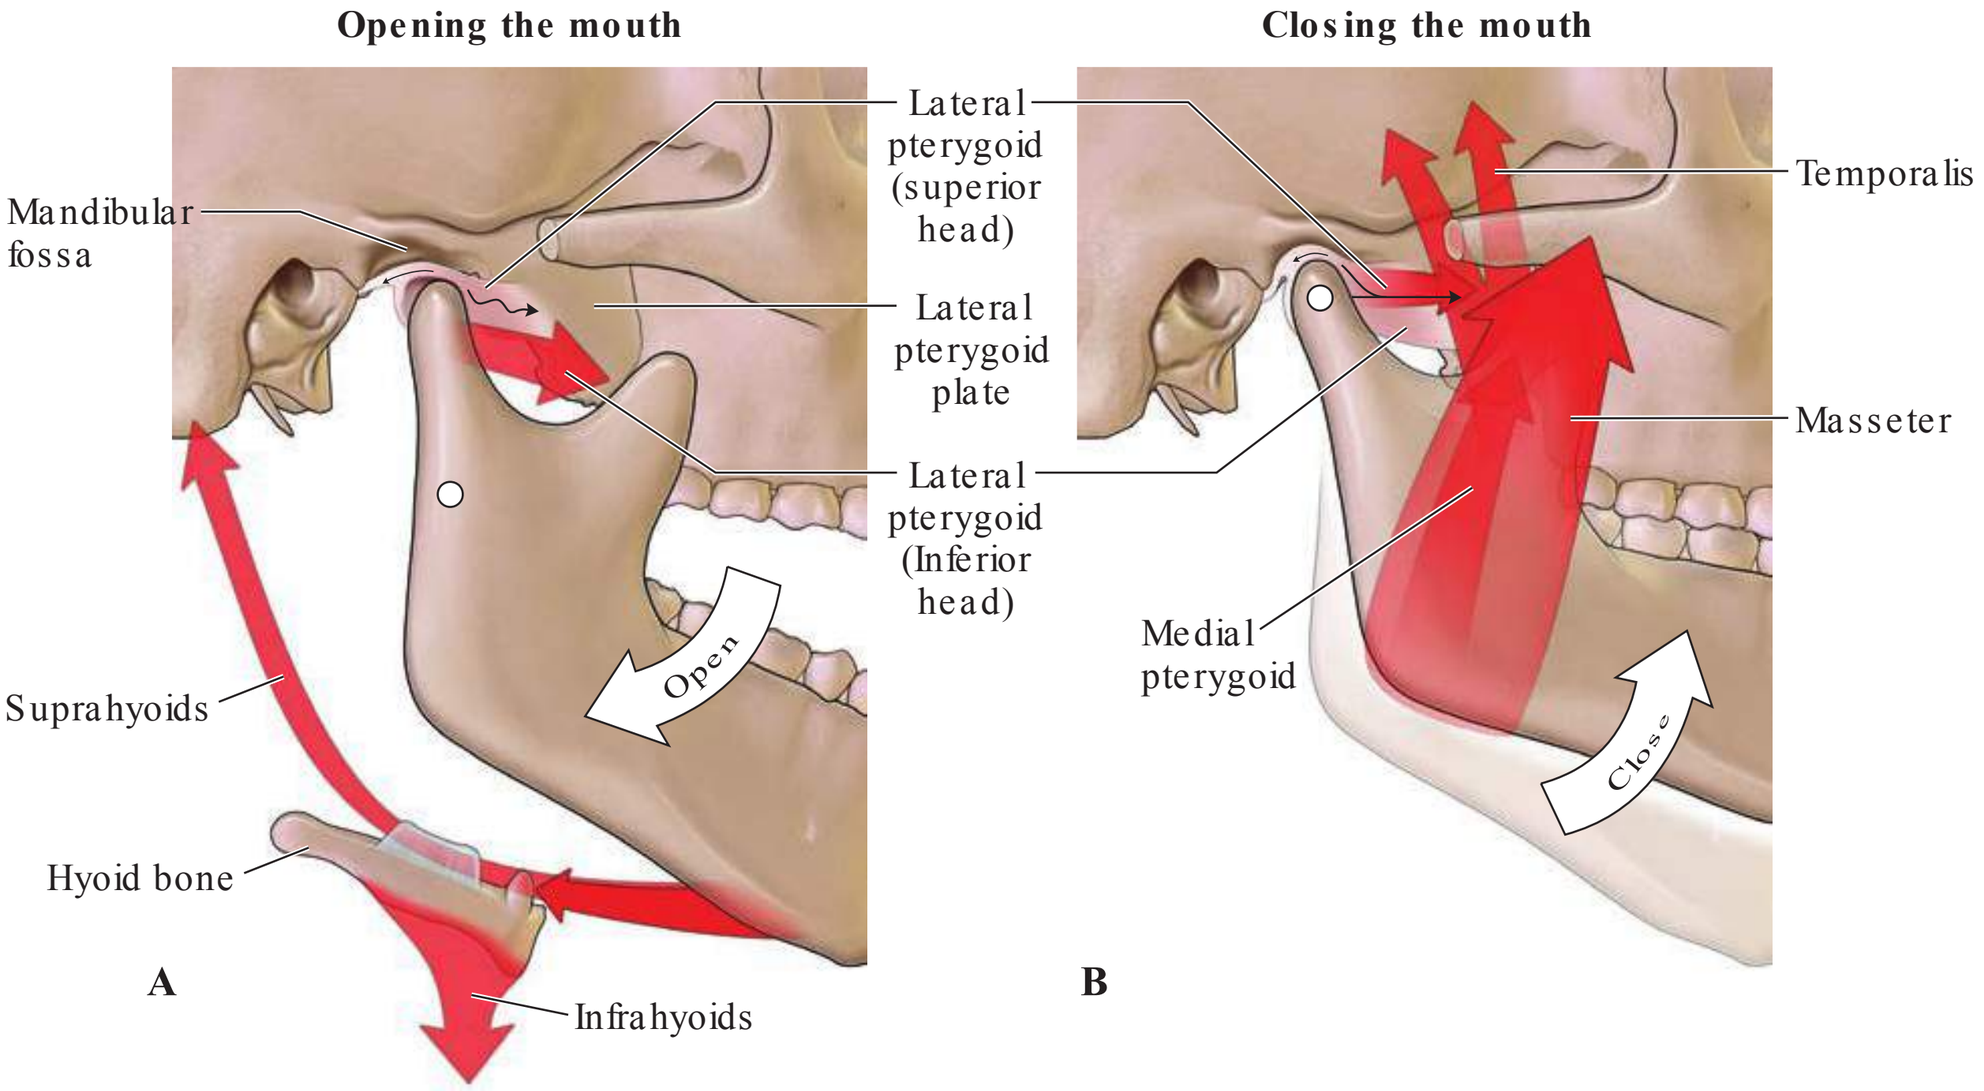

FIGURE 26-8 Mouth opening and closing.

lateral Excursion

If a protrusion movement occurs unilaterally, it is called a lateral excursion, or deviation. For example, if only the left TMJ protrudes, the jaw deviates to the right.

Lateral movements of the mandible are the result of asymmetric muscle contractions (Fig. 26-9). During a lateral excursion to the right, the condyle and the disk on the left side glide inferiorly, anteriorly, and laterally in the sagittal plane and medially in the horizontal plane along the articular eminence. T e condyle and the disk on the right side rotate laterally on a sagittal plane and translate medially in the horizontal plane while remaining in the fossa.

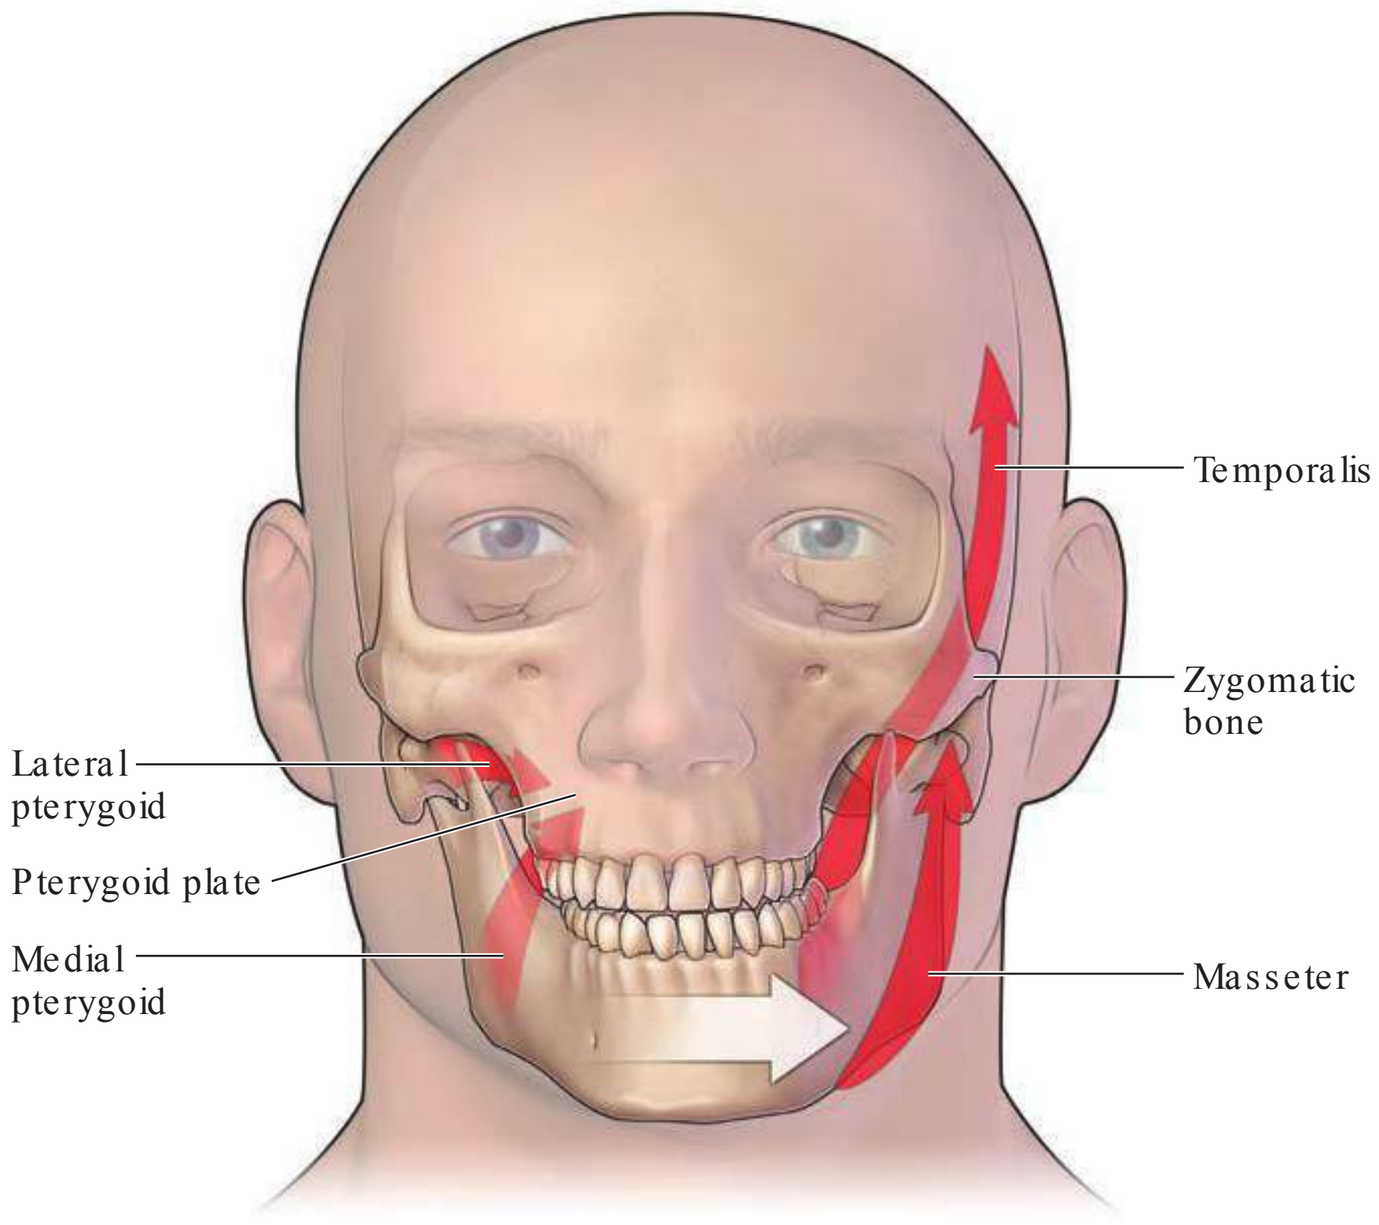

FIGURE 26-9 Lateral deviation to the left.

Clinical Pearl

The translation of the human condyle during jaw opening and lateral jaw movements is referred to as the Bennett shift.

The Close- and Open-Packed (Resting) Positions

The close-packed position of the TMJ is difficult to determine because the position of maximal muscle tightness is also the position of least joint surface congruity and vice versa. Rocabado[56] considers there to be two close-packed positions, named according to the end position of the mandibular head in the fossa:

- Anterior close-packed position. This position is the position of maximum opening of the joint.
- Posterior close-packed position. This position is the maximum retruded position of the joint.

Under this premise, the open-packed, or "rest" position is any position away from the anterior or posterior close-packed positions of the joint.[56] The rest position, or "freeway space" corresponds to the position of the TMJ where the residual tension of the muscles is at rest and no contact occurs between maxillary and mandibular teeth. In this position, the tongue is against the palate of the mouth with its most anterior–superior tip in the area just posterior to the rear of the upper central incisors.[59]

Capsular Pattern

The capsular pattern of the TMJ is a limitation of mouth opening. If one joint is more involved than the other, the jaw will laterally deviate to the same side during opening.

Clinical Pearl

The significance of the rest position is that it permits the tissues of the stomatognathic system to rest and undergo repair.[60]

EXAMINATION

Currently, clinical examination is the gold standard for diagnosing TMDs. Given the multifactorial causes of TMD, a comprehensive examination of the entire upper quadrant, including the cervical spine and shoulders, usually is warranted. In general, the TMJ and the upper three cervical joints all refer symptoms to the head, whereas the mid-to-low cervical spine typically refers symptoms to the shoulder and the arm.[61–63] An accurate diagnosis of TMD involves a careful evaluation of the information gleaned from the history, systems review, and tests and measures. In most chronic cases, a behavioral or psychological examination is required.[3,31,63–68] Since postural dysfunctions are closely related to TMJ symptoms, the clinician should always perform a postural examination as part of a comprehensive examination of this joint. An examination form for the TMJ examination is shown in Table 26-4.

History

A comprehensive history will help identify the possible source(s) of the orofacial pain and provide a screen for other causative or contributing factors.[69] During the history, the clinician should observe whether the patient's mouth moves comfortably. The severity of the symptoms and the time before the symptoms subside can provide the clinician with valuable information regarding possible pathology. Red flags related to cardiac history (e.g., angina or history of myocardial infarction) and brain function (e.g., sudden-onset severe headaches, weakness, or slurred speech) must be investigated early in the history taking.[70]

The clinician should determine from the patient the main reason for the visit. There are three cardinal features of TMDs, which can be local or remote:

- Restricted jaw function. Limited mouth opening, which may be reported as intermittent or progressive, is a key feature of TMD. A key question to determine restricted jaw function is, "Have you ever had your jaw lock or catch so that it would not open all the way? If so, was this limitation in jaw opening severe enough to interfere with your ability to eat? Have you ever noticed clicking, or popping or other sounds in your joint?"[71] Patients may describe a generalized tight feeling, which may indicate a muscular disorder, or capsulitis, or the sensation that the jaw suddenly "catches" or "locks," which usually is related to a mechanical interference within the joint (an internal derangement).[16] Associated signs of an internal derangement include pain and deviation of mandibular movements during opening and closing (refer to Practice Pattern 4D, under "Intervention Strategies" section later), and biting firm objects. Pain in the fully open position is probably caused by an extra-articular problem. Locking may imply that the mouth does not fully open or does not fully close and is often related to problems of the disk or joint degeneration. A gradual onset of symptoms after minor or prolonged physical activity may be indicative of a mechanical derangement. Symptoms of a mechanical nature generally are eased with rest. The irritability of a disorder is determined by the degree of activity necessary to provoke a symptom response.
- Joint noises. Joint noises (crepitus) of the TMJ may or may not be significant, because joint sounds occur in approximately 50% of healthy populations.[72] Some joint sounds are not audible to the clinician, so a stethoscope may be required. "Hard" crepitus is a diffuse sustained noise that occurs during a significant portion of the opening or closing cycle, or both and is an evidence of a change in osseous contour.[57] Clicking describes a brief noise that occurs at some point during opening, closing, or both [see the discussion of range of motion (ROM) testing, later]. Jaw clicking during mouth opening or closing may be suggestive of an internal derangement consisting of an anterior disk displacement with reduction.[73,74]

Clinical Pearl

TMJ sounds should be described and related to symptoms. Joint noise is, of itself, of little clinical importance in the absence of pain.[65,75]

- **Orofacial pain.** TMJ pain should be evaluated carefully in terms of its onset, nature, intensity, site, duration, aggravating and relieving factors, and how it relates to joint noise and restricted mandibular movements. Information about the nature of the pain will be critical in determining the possibility of primary headaches (migraine, cluster) and secondary headaches related to the eyes, ears, sinus, dental structures, medication complications, and/or neurologic types of pain. Unrelenting pain unrelated to musculoskeltal function is an indication for referral. Key

TABLE 26-5 Patient Reports of Pain in TMJ Disorders

Data from Magnusson T, List T, Helkimo M. Self-assessment of pain and discomfort in patients with temporomandibular disorders: a comparison of five different scales with respect to their precision and sensitivity as well as their capacity to register memory of pain and discomfort. J Oral Rehabil. 1995;22:549–556.; Cleland J. Temporomandibular Joint, Orthopaedic Clinical Examination: An Evidence-Based Approach for Physical Therapists. Carlstadt, NJ. Icon Learning Systems, LLC; 2005:39–89. With permission from Icon Learning Systems.

questions have been examined and determined to have strong sensitivity and specificity in incriminating TMDs as the source of pain.[76] The initiating question should be, "Have you had pain or stiffness in the face, jaw, temple, in front of the ear, or in the ear in the past month?"[70] A positive response should be followed by a question about whether the symptoms are altered by any of the following jaw activities: chewing, talking, singing, yawning, kissing, moving the jaw.[69] Specific questions about activities and postures of a sustained nature, such as sitting, sleeping, and driving, should be asked. Orofacial pain associated with mouth opening or closing and jaw crepitus is suggestive of osteoarthrosis, capsulitis, or internal derangement consisting of an anterior disk displacement with reduction.[73,74] Information about cervical dysfunction is essential to determine whether the cervical spine is causing or exacerbating the headache/facial pain.[70] In a study by Magnusson et al.,[77] five different scales of self-assessment of pain were tested in patients with TMJ disorders. The precision and sensitivity and the capacity to register memory of pain and discomfort were compared for each of the five scales (Table 26-5). From these results, the behavior rating scale can be recommended when measuring pain and discomfort in patients with TMJ disorders.

Clinical Pearl

Pain that is centered immediately in front of the tragus of the ear and that projects to the ear, temple, cheek, and along the mandible is highly diagnostic for TMD.[78]

In addition, it is important to determine:

- If the presenting symptoms were caused by trauma or surgery, or if the onset of pain occurred gradually. Questions should focus on any history of trauma during birth or childhood, as well as more recently.
- If there are any emotional factors in the patient's background that may provoke habitual protrusion or muscular tension. Chronic head, neck, and back pain often are associated with psychogenic causes. Psychiatric disorders, usually, are manifested in patients whose afflictions seem to be excessive or persist beyond what would be normal for that condition. The clinician should listen for reports of psychological stress overload, malaise, anxiety, sleep problems, changes in eating patents, weight changes, unexplained fatigue, and other signs of depression, which might exacerbate pain through central mechanisms.[79] The checklist outlined in Table 26-6 can be used by the clinician to identify factors that may warrant an examination by a mental health professional.
- If the patient is aware of any parafunctional habits (cheek biting, nail biting, pencil chewing, teeth clenching, or bruxism). For example, does the patient chew on one side more than the other? Chewing more on one side versus the other is typically the result of malocclusion (see later). In addition, favoring one side can lead to a loss of vertical dimension (the distance between any two arbitrary points on the face). A simple way to measure the aforementioned is to measure from the lateral edge of the eye to the corner of the mouth and from the base of the nose to the chin.
- The behavior of symptoms over a 24-hour period. This information assists the clinician in formulating causal relationships.

TABLE 26-6 Checklist of Psychological and Behavioral Factors

Inconsistent, inappropriate, or vague reports of pain
Overdramatization of symptoms
Symptoms that vary with life events
Significant pain of >6 months' duration
Repeated failures with conventional therapies
Inconsistent response to medications
History of other stress-related disorders
Major life events (e.g., new job, marriage, divorce, and death)
Evidence of drug abuse
Clinically significant anxiety or depression
Evidence of secondary gain

Note: The significance of these factors depends on the particular patient. Data from McNeill C, Mohl ND, Rugh JD, et al. Temporomandibular disorders: Diagnosis, management, education, and research. J Am Dent Assoc. 1990;120:253–260.

- Whether the symptoms are improving or worsening.
- T e relationship of eating to the symptoms. Alcohol, chocolate, and other foods such as ice cream can cause head pain in some individuals, suggesting a vasomotor-related pain.
- T e patient's past dental and orthodontic history.

Systems Review

Pain or dysfunction in the orofacial region often results from nonmusculoskeletal causes such as otolaryngologic, neurologic, vascular, neoplastic, psychogenic, and infectious diseases. Clinicians often see patients with a TMD who present with nonspecific symptoms such as neck pain, headaches (see Chapter 5), earaches, tinnitus, and sinusitis.[70] Patients with sinusitis complain of acute facial pain or pressure type headaches, and may present with nasal congestion, a reduced sense of smell, postnasal drip, fever or malaise, and aching teeth associated with certain weather conditions or times of the year.[80] Ear disorders, such as an inner or outer ear infection, can produce pre-auricular symptoms in around the TMJ.[81] Conversely, hyperactivity of the masticatory and tensor tympani muscles can cause ear pain, tinnitus, and feelings of fullness in the ear.[82] Finally, patients with eye disorders may experience pain around the eye, numbness, a headache, and other symptoms similar to TMD, a cervicogenic headache (see Chapter 23), or a primary headache (see Chapter 5).[70]

Unexplained weight loss, ataxia, weakness, fever with pain, nystagmus, and neurologic deficits are characteristic of intracranial disorders.[83] Neurovascular disorders are associated with a migraine headache and its variants, carotidynia, and cluster headaches (see Chapter 5). Neuropathic disorders include trigeminal neuralgia, glossopharyngeal neuralgia, and occipital neuralgia.

A cranial nerve screen (see Chapter 3) should be completed on each patient presenting with orofacial pain with particular attention on the fifth cranial nerve (trigeminal), which supplies motor and sensory innervation to the masticatory region.

Once the possibility of cervical, systemic, psychogenic, or ear or sinus problems has been ruled out, the next step is to consider the possibility of TMJ pain and impairment.

Tests and Measures

Examination of the TMJ structures includes observation, and a thorough mobility and palpation examination to identify impairments and functional limitations.

Observation

T e posture of the head and neck are assessed for asymmetry. T e forward head posture (FHP–see Chapters 6 and 25) frequently is associated with TMD.[34,84,85] T is is likely because of the direct impact an FHP can have on oral symmetry during occlusion. Occlusion occurs when the teeth are in contact and the mouth is closed—when tapping the teeth together in the neutral position, all of the teeth appear to strike simultaneously. However, if the same task is attempted while placing the head forward, it is the anterior teeth that occlude first. A deviation from normal occlusion is defined as malocclusion—improper positioning of the teeth and jaws. Malocclusion is a variation of normal growth and development which can affect the bite, the ability to clean teeth properly, gum tissue health, jaw growth, speech development, and appearance. T e consequences of this repetitive functional malocclusion during food or gum chewing should be apparent. A chronic FHP may result in an adaptive shortening of the deep cervical fascia and muscles, which can exaggerate the functional malocclusion. Most people have some degree of malocclusion, although it is not usually serious enough to require treatment. Malocclusions can be divided mainly into three types, depending on the sagittal relations of teeth and jaws, by Angle's classification method, which is based on the relative position of the first maxillary molar[86]:

- Class I (Neutroclusion): T e molar relationship of the occlusion is normal, but the other teeth have problems such as spacing, crowding, and over or under eruption.
- Class II (Distoclusion): T e upper molars are placed anteriorly. T ere are two subtypes:
  - Class II Division 1 (large overjet): T e molar relationships are like that of Class II and the anterior teeth are protruded.
  - Class II Division 2 (deep overbite): T e molar relationships are like that of class II but there is lateral flaring of the lateral maxillary incisors.
- Class III (Mesioclusions): T e lower front teeth are more prominent than the upper front teeth. In this case, the patient very often has a large mandible or a short maxillary bone.

T e clinician should also note whether the teeth are normally aligned or whether there is any crossbite, underbite, or overbite.

- Crossbite: T is occurs when the teeth of the mandible are lateral to the upper maxillary teeth on one side and medial on the opposite side. An anterior crossbite occurs when the lower incisors are anterior to the upper incisors, whereas a posterior crossbite occurs when there is a abnormal transverse relationship of the teeth.
- Underbite: T is occurs when the mandibular teeth are anterior to the maxillary teeth either unilaterally, bilaterally, or in pairs.
- Overbite: T is occurs when the anterior maxillary incisors extend below the anterior mandibular incisors when the jaw is in central occlusion.

Cl In ICAl PEARl

Overjet, not to be confused with an overbite, is a measure of how far the top incisor teeth are ahead of the bottom incisors. Normally, the top and bottom front teeth should be touching upon closure leaving no or zero overjet. If the top teeth are ahead by some distance, this is referred to as positive overjet. If the top teeth are behind the bottom teeth, this is referred to as negative overjet or underjet.

T e face is also assessed for asymmetry, such as swelling or flattening of the cheek. Asymmetry is an important finding, because developmentally the facial structures evolve in a proportional relationship, some determined by genetics, others in response to the physical environment.[87] Orthognathy relates to the amount of projection of the lower face in relation to an imaginary perpendicular line from the eyes when viewed from the side. T ree types of facial profile are recognized:

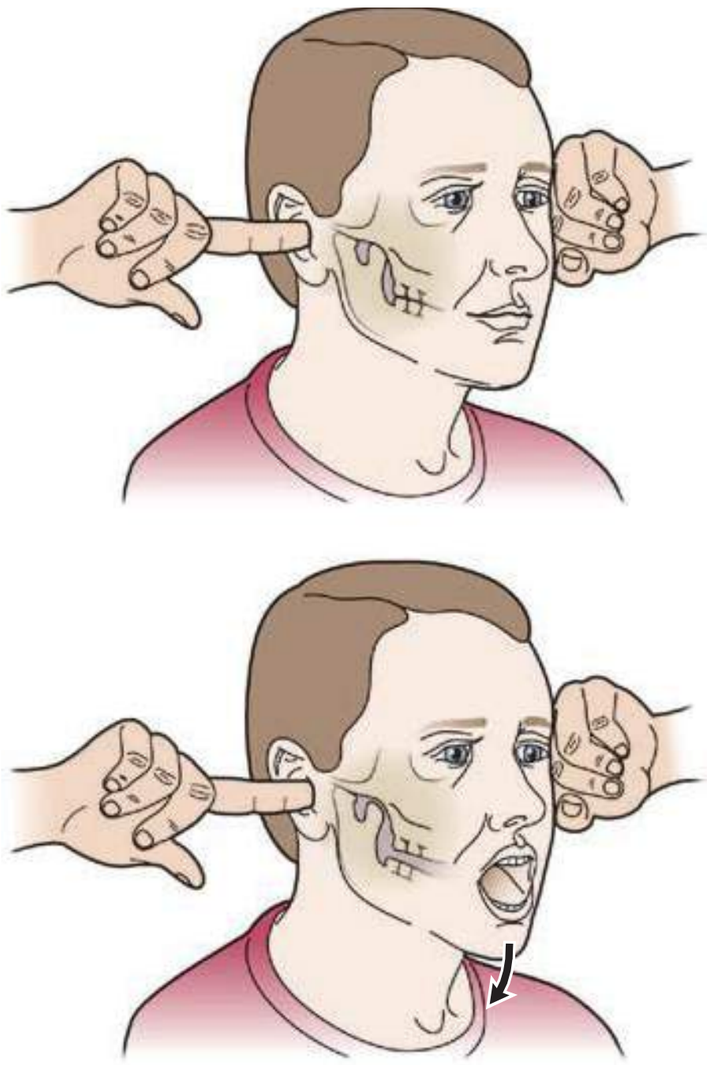
- Orthognathic: A straight facial profile in which the upper and lower lips are in line with the tip of the chin.
- Retrognathic: Describes a facial profile in which the tip of the chin is posterior to the upper and lower lips.
- Prognathic: Describes a facial profile in which the tip of the chin is anterior to the upper and lower lips.

In addition, the clinician should note the presence of any abnormal jaw deviation, unusual dryness of the lips, changes in eye position, and signs of tissue stress such as overdeveloped masseter and mentalis muscles, or a hypertrophied lower lip.[32] A lateral deviation of the jaw, evidenced by a malalignment or malocclusion of the upper and lower teeth, or hypertonus of one of the masseter muscles, may cause an adaptive shortening of the mastication muscles on the ipsilateral side of the deviation, and a lengthening of the muscles on the contralateral side. Since the role that malocclusion plays in TMD remains unclear, the relevance of the malalignment to the patient's symptoms must be determined by passively attempting to correct the deformity.[54,58] An increase in pain with the correction suggests the presence of a protective deformity.

T e teeth should be examined for symmetry. Cavities, wear patterns, and restored, and missing teeth should be noted. Defects in dimensions can be measured radiographically.[88] T e vertical dimension of dental occlusion (i.e., depth of bite) has been implicated as a possible craniomandibular component associated with TMD.[37] It has been proposed that a deep dental overbite may have pathologic effects on cranial nerve V, the tensor veli palatini, and the soft-tissue surrounding the TMJ.[37,89] Seldin[90] and Sicher[91] proposed that a deep bite results in a displaced condyle, which causes inflammation and muscle spasm in the retrodiskal tissue and muscles surrounding the TMJ. Tooth wear and fracture are often destructive signs of parafunctional habits (abrasive diet, bruxism, and teeth clenching). Loss of teeth can cause disruption in the working and nonworking interfaces of the teeth, which may cause unilateral function and subsequent overloading of the remaining teeth and the TMJ.[17] T e clinician should also ask the patient if there are any painful or sensitive teeth, which can lead to incorrect biting and subsequent abnormal loading of the TMJs.

T e tongue should be examined. T e tongue should appear dull red, moist, and glistening. Its anterior portion should have a smooth yet roughened appearance.[92] T e posterior portion should have a smooth, slightly uneven appearance.

- A hairy tongue with yellow–brown to black elongated papillae on the posterior surface sometimes follows antibiotic therapy.[92]
- A dry or white tongue may indicate a salivary gland dysfunction or an oral yeast or bacterial infection respectively.[92]



T e tongue should be observed while the patient swallows to check for any deviations. T e tongue is tested for frenulum length. A short frenulum may interfere with tongue function. T e tongue should have no difficulty in touching the hard palate behind the upper incisors.[53] A large tongue can exert excessive pressure against the teeth and may interfere with occlusion, resulting in bite marks.

T e rest position of the TMJ should be noted. T e clinician can locate the rest position of the TMJ by gently placing the little finger with the palmar portion facing anteriorly into the external auditory meatus. From an open-mouth position, the patient is asked to slowly close the mouth. At the point of resting position, the patient's mandibular heads are felt to gently touch the finger. T e space between the upper and lower incisors should be 2–4 mm. A greater distance may indicate hypermobility of both TMJs.

Range of Motion

T e ROM of the TMJ, the cervical spine, the craniovertebral joints, and the shoulders should be assessed with active ROM (AROM), and then with passive overpressure, to assess the end-feel. During cervical flexion, the mandible moves superiorly and anteriorly, whereas, during cervical extension, the mandible moves inferiorly and posteriorly. T e patient should be able to open and close the mouth while keeping a fist in place under the chin. During side bending or rotation of the cervical spine, a maximum occlusion occurs on the ipsilateral side. Although it is unclear how the individual components of the examination contribute to the final diagnosis, most clinicians would agree that substantially reduced mandibular motion is a strong indicator of the presence of a serious TMD and helps to distinguish TMD patients from non-TMD controls.[93,94] However, there is little evidence to suggest that mandibular motion measurements add critical information to the process of differential diagnosis among the common TMD subgroups.[93]

T e clinician observes the opening and closing of the mouth, noting both the range and the quality of movement. All movements of the TMJ should be smooth and without noise or pain. Normally, the mandible should open and close in a straight line. To help detect crepitus, the clinician can palpate over the mandible heads during opening and closing (Fig. 26-10). If crepitus or clicking occurs on opening and/or closing, the clinician notes where they occur in the range. If pain occurs, a determination should be made as to where in the range the pain occurs, and the location of the pain. A Boley gauge, T-bar, or ruler, can be used to measure the range of the TMJ in millimeters. Walker et al.[95] used a prospective descriptive study to determine the discriminant validity and intra- and interrater reliability of measurements of TMJ ROM using a ruler. Two groups of subjects were tested: 15 subjects (two men, 13 women; mean age = 35.2 years) with a TMD and 15 subjects (three men, 12 women; mean age = 42.9 years) without a TMD. Six motions were measured (opening, left lateral deviation, right lateral deviation, protrusion, overbite, and overjet) by two physical therapists. T e study concluded that mouth opening was the only TMJ ROM measurement to discriminate between subjects with and without a TMD (mean 36.2 ± 6.4 vs. 43.5 ± 6.1 mm). T e technical

Palpatation during opening

FIGURE 26-10 Palpation of TMJ during mouth opening and deviation.

error of measurement of the measures varied from 0.2 to 2.5 mm. Intrarater reliability coefficients (ICC 3, 1) varied from 0.70 to 0.99. Interrater reliability coefficients (ICC 2, k) varied from 0.90 to 1.0.

Cl In ICAl PEARl

Joint clicking can be a normal occurrence or it may be caused by one of the types of internal derangement (refer to Practice Pattern 4D, later) including disk displacements, adhesive disk hypomobility, and deviation in form (articular surface damage). Clicking may also be a result of hypermobility or muscle incoordination.[96]

T e type and temporal sequence of joint clicking can provide the clinician with the following information[70]:

- Reciprocal clicking is defined as clicking that occurs during opening and again during closing. T e opening click occurs when the condyle moves under the posterior band of the disk until it snaps into its normal relationship on the concave surface of the disk, whereas the closing click reflects the reversal of this process. Reciprocal clicks may be early, intermediate, or late, depending on the degree of opening at which they occur.
  - Early clicking usually indicates a small anterior displacement.
  - Late clicking usually indicates that the disk has been further displaced.

Reciprocal clicking is a common finding in patients with a posterosuperior condylar positioning.

- Clicking that occurs at the end of opening often results from articular hypermobility and is accompanied by a deviation of the jaw toward the contralateral side.
- T e "soft" and "popping" opening and closing clicks associated with muscular incoordination are usually intermittent and inconsistent. T ey are thought to be caused by ligament movement or articular surface separation. Muscle tenderness to palpation is a frequently associated symptom.

Elevation of the Mandible (Mouth Closing)

T e primary muscles involved with mouth closing are the masseter, the temporalis, and the medial pterygoid.[53] Since the maxillary teeth are fixed, the upper midline of the incisors can be used as a landmark to assess lower jaw deviation during mouth closing. Under normal conditions, the midline relationship between the upper and lower incisors should remain constant in the closed and open positions. Overpressure can be applied to the mouth closing by placing the fingers under the chin and pushing superiorly in a controlled fashion (Fig. 26-11). T e normal end-feel for mouth closing should be bone on bone (teeth contact).

Depression of the Mandible (Mouth Opening)

T e opening of the mouth is considered the most revealing and diagnostic movement for TMD.

While approximately only 25–35 mm of mouth opening measured between the maxillary and mandibular incisors is required for everyday activities, the maximum ROM is approximately 40–50 mm.[95] At this extreme, the periarticular structures are stretched to 100% of their total length. T e functional ROM is considered to be closer to 40 mm,

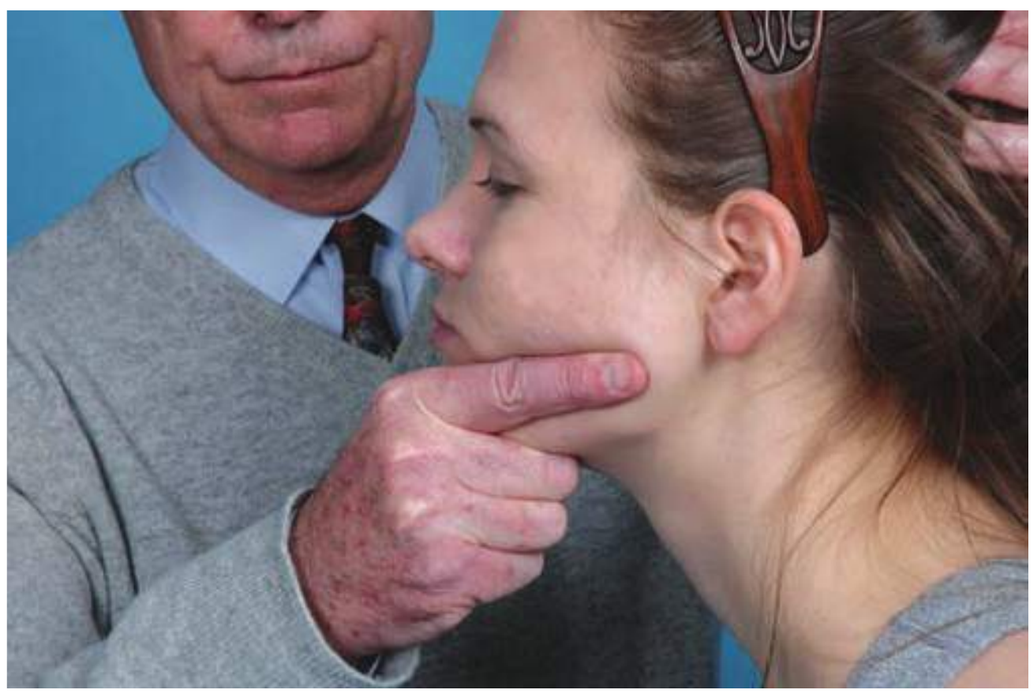


FIGURE 26-11 Mouth closing with overpressure.

FIGURE 26-12 Three-knuckle width of mouth opening.

or approximately a two-to-three-knuckle width of the non-dominant hand[16] (see Fig. 26-12). At this point in the range, the periarticular structures are stretched to 70–80% of their total length. Excessive opening is indicated when the patient is able to insert three or more knuckles between the incisors. Excessive opening is associated with large anterior translatory movements at the beginning of mouth opening, accompanied by excessive protrusive movements of the mandible. Linear ruler measurement of mandibular opening has good intrarater and interrater reliability (ICC = 0.70–0.99 and 0.90–1.00, respectively).[95]

If a deviation occurs to the left on opening (a C-type curve) or to the right (a reverse C-type curve), hypomobility is evident toward the side of the deviation. If, during mouth opening, an S-type or reverse S-type curve is noted, the problem is probably a muscular imbalance or medial displacement of the disk. Reduced mouth opening can result from a number of disorders including chronic muscle contraction, ankylosis, acute disk displacement without reduction, and severe trismus of the jaw muscles (the limitation of jaw opening caused by spasm of the masticatory muscles) and gross osteoarthritis.[97] Muscle contractures and ankylosis tend to develop after a substantial trauma or are developmental disorders occurring early in life and are not often misdiagnosed.[97] If contracture of the masticatory muscles is present, the mandibular opening can be as limited as 10–20 mm between the incisors.[98] Acute disk displacement without reduction and trismus are difficult to distinguish because both conditions present with recent onset and painful limitation of jaw opening.[93] To be certain of the anatomic basis of acute disk displacement without reduction, most clinicians feel that joint imaging with magnetic resonance of the disk is required.[74,93,99] A limited opening of the jaw may also indicate joint hypomobility, muscle tightness, or the presence of trigger points within the elevator muscles: the temporalis, the masseter, and the medial pterygoid.

Translation of the lateral pole of the condyle should occur after 11 mm of mouth opening. If an opening deviation occurs, it is important to note where in the opening cycle it occurs. Opening and closing deviations are observed simply by taking a small ruler or tongue depressor and laying the edge down the midline of the face.[57] While the clinician "eyes" the straight edge, the patient opens and closes the mouth slowly[96]:

- Limited opening with deviation to one side should alert the clinician to an internal derangement without reduction, which limits the translation on the involved side and causes the jaw to deviate toward the less-mobile side, even if that is the normally mobile side and the other side is hypermobile. Early deviation suggests hypomobility, and late deviation indicates hypermobility.
- If hypomobility resulting from internal derangement with reduction of one TMJ is present, the mandible will deviate in a C pattern of motion to that side of the open mouth in the midrange of opening before returning to normal.
- The patient who demonstrates an S movement of the jaw while opening the mouth may have a muscle imbalance (often caused by trigeminal facilitation and masticatory hypertonicity), or it may be a momentary locking of a deranged disk. Lateral excursion of the mandible with mouth opening implicates contralateral structures such as the contralateral disk, the masseter, the medial and lateral pterygoid, or the lateral ligaments.

Overpressure can be applied to the opening movement using a lumbrical grip placed on the patient's chin, under the bottom lip (Fig. 26-13). The overpressure is applied to ensure that the jaw is maximally depressed. The normal end-feel should be tissue stretch. Locking of the jaw can be associated with three types of abnormal end-feel[57]:

- Hard. This type of end-feel is associated with osseous abnormalities.
- Springy. This type of end-feel is associated with a displacement of the disk.
- Capsular. This type of end-feel is associated with adaptive shortening of the periarticular tissues.

Excursion of the Mandible

The superior and inferior incisors are assessed for any deviation of the jaw laterally (crossbite) or anteroposteriorly (overbite or underbite).

Protrusion of the Mandible. The patient opens the mouth slightly and protrudes the lower jaw. The normal movement of the lower teeth is greater than 7 mm, measured from the resting position to the protruded position. This is equates to the

FIGURE 26-13 Mouth opening with overpressure.

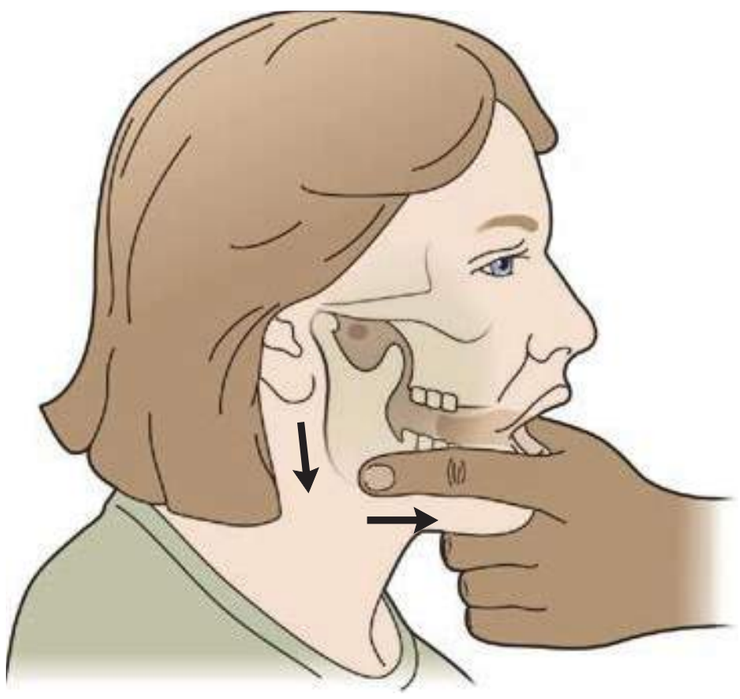

FIGURE 26-14 Manual jaw protrusion.

mandibular teeth being able to protrude past the top teeth. T e amount and direction of the protrusion are noted:

- An abnormal protrusive position may be associated with a residual pediatric tongue thrust (deviant swallowing), or an acquired adult tongue thrust secondary to a forward head posture or habitual protrusion.
- Any lateral excursion of the mandible during protrusion may indicate the involvement of the contralateral structures, such as the contralateral disk, the masseter, the medial and lateral pterygoid, or the lateral ligaments.

T e clinician can apply overpressure by grasping the patient's mandible with the index and the middle fingers behind the mandibular angles and the thumbs on the patient's cheeks, and then gently pulling the jaw anteriorly (Fig. 26-14).

Retrusion of the Mandible. T e patient is asked to retrude the jaw as far back as possible. T e normal movement is 3–4 mm.[58] Pain at the end range of retrusion may indicate an intracapsular injury.[8] Overpressure can be applied using a lumbrical grip positioned under the patient's bottom lip and pushing the mandible posteriorly (Fig. 26-15).

Lateral Deviation of the Mandible. T e patient opens the mouth slightly and moves the lower jaw to the left and to the right. T e right and left motions are compared. Normal ROM for lateral deviation is approximately one-fifth of the opening range (8–11 mm).[35] Lateral deviation can be measured as the amount of lateral excursion between the center of the mandibular incisors and the center of the maxillary incisors. An appreciable difference between the two sides is more significant than a limited range occurring bilaterally.[32] Passive overpressure can be applied in a lateral direction. Pain reported on the side away from the direction of overpressure may indicate ligamentous or joint capsule damage.[32]

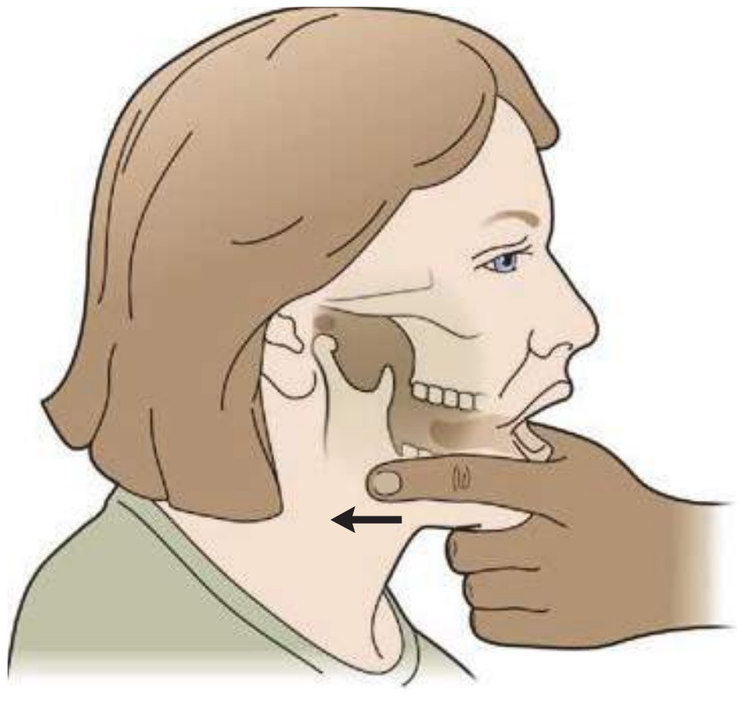

FIGURE 26-15 Manual jaw retrusion.

Tongue Movements. Tongue movements give valuable information about the function of the hypoglossal nerve (CN XII). Any deviation or atrophy of the tongue during tongue protrusion may indicate a lesion of this nerve. A unilateral weakness of the tongue is manifested by a deviation of the protruded tongue toward the weaker side. A test for a weakness of the tongue is to ask the patient to stick the tongue into the cheek while the clinician presses against the bulging cheek. A comparison is made between both sides.

Palpation

Palpation of the TMJ can be used to assess tenderness, patterns of pain referral, skin temperature, muscle tone, swelling, skin moisture, and the location of trigger points. T e palpation examination begins with a gentle touch and light pressure because the muscles of mastication can be highly sensitive if they are in spasm. Schiffman et al.[71] found that a range of about 1–1.8 kg (approximately 2–4 lb of force) is appropriate for masticatory joint and muscle palpation examination. Clinician should use slight blanching of the pad of the distal phalanx as a guideline for appropriate amounts of pressure during the palpation examination.[70] In a study by Manfredini et al.,[100] 61 patients with TMJ pain were assessed by means of a standardized clinical examination and magnetic resonance imaging (MRI). T e aim of this work was to evaluate the predictive value of clinical symptoms for MRI findings of TMJ effusion. T e study reported that a clinical examination based on the assessment of pain in the TMJ with lateral palpation, with posterior palpation, during motion, and during maximum-assisted opening, and the presence of click and crepitus sounds demonstrated an accuracy of 78.7% to predict TMJ effusion. Among the single clinical symptoms, the most reliable predictor of TMJ effusion was found to be the presence of pain with lateral palpation (accuracy 76.2%; kappa = 0.53).[100] T e two primary positive findings with palpation in this region are local tenderness and pain referral, although it is difficult to determine whether the muscle pain is the primary source of the problem or a secondary condition contributing to the overall pain condition.[101]

T e TMJ should be palpated at rest and during mandibular motion. For comparison and expediency, palpation of the lateral and posterior aspects of the TMJs is performed bilaterally and simultaneously.

Anterior Aspect

Zygomatic Arch. T e zygomatic arch is located anterior to the condylar process of the mandible. T e temporal muscle lies above, and the masseter muscle lies below the zygomatic arch.

Hyoid Bone. T e hyoid bone, located anterior to the C2 and C3 vertebrae, is palpated for normal, painless movement as the patient swallows.

Digastric Muscle (Anterior Belly). T e anterior belly of the digastric muscle can be palpated from its origin on the lingual side of the mandible to its tendinous insertion on the hyoid bone.

Thyroid. T e thyroid cartilage, located anterior to the C4 and C5 vertebrae, is palpated and moved. Crepitation of this structure may be felt during neck extension as the cartilage becomes taut.

l ateral Aspect

Temporomandibular Joint. T e clinician palpates the lateral aspect of the TMJ by placing the tip of the forefinger just anterior to the tragus of the ear (see Fig. 26-10). During mouth opening, the lateral pole of the condyle is the most palpable osseous structure. As the individual opens the mouth wide, the clinician's finger will identify a depression posterior to the condylar head (the posterior aspect of the joint) and overlying the joint that is created by the translating condyle. Tenderness in this depression may indicate inflammation.[32] Alternatively, the lateral aspect of the joint capsule can be palpated on the lateral pole of the condyle just anterior to the tragus. To facilitate identification of the lateral pole, the patient is asked to open and lightly hold a cotton roll in the premolar region.[93] palpation around the lateral pole had excellent inter-rater reliability for pain reproduction (kappa= 0.89)[71] and is part of the DC/TMD classification algorithm for any joint pain, with sensitivity and specificity of 0.92 and 0.96 when using the expert driven diagnosis as the gold standard (and high patient accuracy).[71]

Mandible. T e mandible should be palpated along its entire length. Any asymmetry from side to side should be noted. T e mandibular angle serves as an important landmark for orientation. T e mandibular ramus is covered by the masseter muscle. T e condylar process of the mandible is located just in front of the ear. T e parotid gland is located anterior to and below the auricle, and normally extends from the sternomastoid muscle anteriorly to the masseter muscle. Enlargement of the parotid gland causes the earlobe to move outward on the involved side. Enlargement of the parotid gland can have a number of causes, including infection, trauma, diabetes mellitus, lymphoma, or chronic alcoholism.[92] T e submandibular gland is palpable in front of the mandibular angle and underneath the mandibular body, about halfway between the chin and the mandibular angle. Normally, the gland has a firm, irregular consistency.

Sternocleidomastoid Muscle. T e sternocleidomastoid is palpated from its dual origin on the sternum and the clavicle along its course upward and posteriorly to its insertion on the mastoid process.

Trapezius Muscle. T e trapezius muscle is palpated from its origin on the acromion process to its insertion along the midline of the spine to the base of the skull. T e trapezius is perhaps the most common site for muscular trigger points and often refers pain to the base of the skull and the temporal region.[102]

Masseter Muscle. Both the superficial and deep portions of the masseter run from the zygomatic arch to the mandibular ramus. Palpation begins at the superior attachment along the zygomatic arch and continues inferiorly along the muscle belly to its inferior attachment on the ramus of the mandible. Trigger points in the masseter muscle can refer pain to the teeth, ear, and sinus areas.[102]

Temporalis Muscle. T e temporalis muscle can be palpated in front of, and above, the ear. T e clinician places a finger against the temporal region and then asks the patient to gently open the mouth. T e anterior vertical, middle oblique, and posterior horizontal clench the teeth fibers should all be palpated. T e temporalis can refer pain to the teeth, the joint, and the retro-orbital area.[102] T e tendon can be palpated intraorally and extraorally during mandibular depression to bring the coronoid process inferior to the zygomatic arch.[81]

Posterior Aspect of the Joint. Posterior TMJ palpation is performed by placing the tip of the little finger in the patient's external auditory canal and exerting anterior pressure as the patient repeatedly opens and closes the mouth.[32] Alternatively, the palpation can be performed with the teeth in the intercuspal position.[93] If inflammation is present, pain is felt on jaw closing as the tissue is compressed between the clinician's finger and the condyle.[31] T e examination also may reveal a posterosuperiorly positioned condyle and disk dysfunction. T is posterosuperior position of the condyle can be a result of occlusal factors or trauma. T e position results in an anteriorly displaced disk and an impingement by the condyle on the space normally occupied by the disk. T is displacement may cause reciprocal clicking or locking.

T e masseter, temporalis, and perihyoid muscles are palpated extraorally for hypertonicity and tenderness. In addition, the lateral aspect of the joint capsule and the lateral TMJ ligament are palpated for tenderness.

Medial and Lateral Pterygoid. It is questionable whether the medial lateral pterygoid can be palpated due to the depth of their location and adjacent overlying structures. Nonetheless, descriptions detailing palpation of these muscles exist. For the medial pterygoid, the patient is asked to move the tongue to the opposite side. T e clinician slides a thumb onto the medial aspect of the lower gum and toward the back of the mouth and angle of the mandible. T e thumb is maintained at the bottom of the mouth to prevent the gag reflex. T e insertion site for the medial pterygoid is located on the medial aspect of the mandibular angle. T e lateral pterygoid is said to be palpated by sliding a thumb back to the medial aspect of the base of the upper molars. T e patient is asked to open the mouth wider, and the clinician slides the thumb back and up at an angle of 45 degrees and inspects the muscle and area for tenderness.

Muscle Tests

It is important to be able to stress the muscles of mastication and facial expression selectively to determine whether they are implicated in the symptoms. All these tests cannot replace a thorough palpation of the muscles. All test positions, resisted motions, and attempted facial expressions may be used as exercises to rehabilitate any identified deficits. For each of the following, the patient is seated.

Temporalis

The clinician palpates the side of the head in the temporal fossa region. The patient is asked to elevate and retract the mandible. Resistance can be applied using a tongue depressor placed between the teeth. Both sides are tested.

Masseter

The clinician palpates the cheek, just above the angle of the mandible. The patient is asked to elevate the mandible, as in closing the jaw. Resistance can be applied using a tongue depressor placed between the teeth.

Lateral Pterygoid

The clinician palpates the pterygoid at the neck of the mandible and joint capsule. The patient is asked to protrude and depress the mandible against manual resistance.

Medial Pterygoid

The patient is asked to elevate and protrude the mandible. Resistance can be applied using a tongue depressor placed between the teeth.

Suprahyoid Muscles

The clinician palpates the floor of the mouth. The patient is asked to press the tip of the tongue against the front teeth. Resistance can be applied to the surface of the hyoid bone in an attempt to protrude the tongue.

Infrahyoid Muscles

The clinician palpates below the hyoid bone, immediately lateral to the midline. The patient is asked to swallow while the clinician palpates for the movement of the hyoid and the larynx.

Muscles of Facial Expression

This group of muscles, most of which are innervated by the facial nerve, can be assessed by having the patient attempt to make the specific facial expression attributed to each muscle (Table 26-7). Facial strength can be evaluated with the House–Brackmann facial nerve grading system[103–106] (Table 26-8), which separates facial nerve paralysis into six grades, based on the severity of findings. In 1985, the American Academy of Otolaryngology, Head and Neck Surgery adopted the House–Brackmann six-point subjective grading scale as a universal standard. Parameters evaluated during the examination include:

- overall macroscopic and gross appearance;
- appearance at rest;
- forehead movement;
- eyelid closure;
- mouth appearance;
- synkinesis contracture or hemifacial spasm, or both.

Ligament and Capsule Stress Tests

The ligament stress tests assess the integrity of the capsule and ligaments. Positive findings include excessive motion compared with the other side, or pain. The patient is seated or supine.

TABLE 26-7 Muscles of Facial Expression

Muscle	Action	Innervation
Occipitofrontalis	Wrinkles forehead by raising eyebrows	Facial nerve
Corrugator	Draws eyebrows together, as in frowning	Facial nerve
Procerus	Draws skin on lateral nose upward, forming transverse wrinkles over bridge of the nose	Facial nerve
Nasalis	Dilates and compresses aperture of the nostrils	Facial nerve
Orbicularis oculi	Closes eyes tightly	Facial nerve
Superior levator palpebrae	Lifts upper eyelid	Oculomotor nerve
Orbicularis oris	Closes and protrudes lips	Facial nerve
Major and minor zygomatic	Raises corners of mouth upward and laterally, as in smiling	Facial nerve
Levator anguli oris	Raises upper border of lip straight up, as in sneering	Facial nerve
Risorius	Draws corners of mouth laterally	Facial nerve
Buccinator	Presses cheeks firmly against teeth	Facial nerve
Levator labii superioris	Protrudes and elevates upper lip	Facial nerve
Depressor anguli oris and platysma	Draws corner of mouth downward and tenses skin over neck	Facial nerve
Depressor labii inferioris	Protrudes lower lip, as in pouting	Facial nerve
Mentalis	Raises skin on chin	Facial nerve

TABLE 26-8 House–Brackmann Facial Nerve Grading System

Parameter	Grade I	Grade II	Grade III	Grade IV	Grade V	Grade VI
Overall appearance	Normal	Slight weakness on close inspection	Obvious but not disfiguring difference between both sides	Obvious weakness and/or disfiguring asymmetry	Only barely perceptible motion	No movement
At rest	Normal symmetry	Normal symmetry	Normal symmetry	Normal symmetry	Asymmetry	Asymmetry
Forehead movement	Normal with excellent function	Moderate-to-good function	Slight-to-moderate function	None	None	None
Eyelid closure	Normal closure	Complete with minimum effort	Complete with maximal effort	Incomplete closure with maximal effort	Incomplete closure with maximal effort	No movement
Mouth	Normal and symmetric	Slight asymmetry	Slight asymmetry with maximum effort	Asymmetry with maximum effort	Slight movement	No movement
Synkinesis contracture and/or hemifacial spasm	None	May have very slight synkinesis; no contracture or hemifacial spasm	Obvious but not disfiguring synkinesis contracture and/or hemifacial spasm	Synkinesis contracture and/or hemifacial spasm disfiguring or severe enough to interfere with function	Synkinesis contracture and/or hemifacial spasm usually absent	No movement

Temporomandibular (lateral) ligament

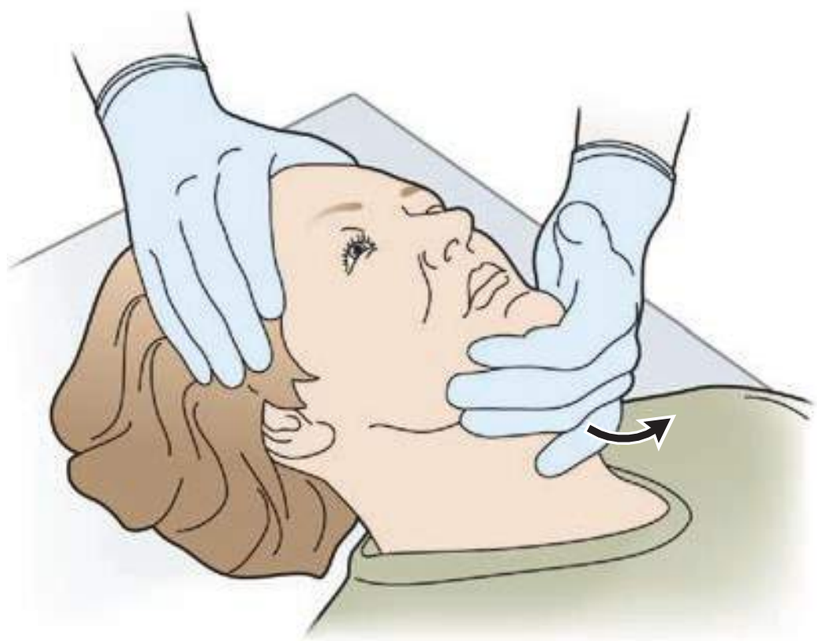
This test is only performed if there is a painful loss of AROM of the TMJ. The purpose of the test is to determine if the painful restriction is caused by damage to one of the ligaments or the joint capsule.

The clinician cradles and stabilizes the patient's head with one hand. The index and middle fingers of this hand can be used to palpate the joint line. The patient is asked to open their mouth to the point of restriction; mandible is positioned slightly open. The clinician places the thumb of the mobilizing hand on the ipsilateral molars of the side to be tested. The clinician then applies a downward force on the molars creating a caudal shear (Fig. 26-14). There should be slight movement with this technique, and the end-feel should be capsular.

Joint Capsule

The clinician stands at the head of the patient. The patient's mandible is closed. The clinician places one hand on top of the patient's head, and the other hand on the ramus and angle of one side. The clinician then applies a contralateral protrusion and ipsilateral deviation force (Fig. 26-16).

Joint loading Tests



Selective loading of the TMJ may be used to help determine the presence of an intracapsular pathology. A positive finding is a pain with the test. These tests include dynamic loading and joint compression.[53]

Dynamic loading

The patient is asked to bite forcefully on a cotton roll or tongue depressor on one side. This maneuver loads the contralateral TMJ.

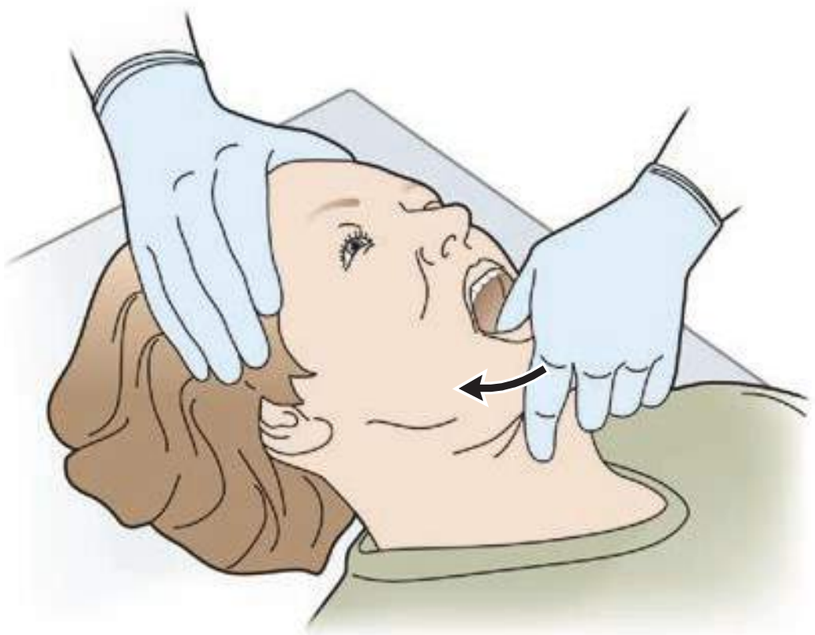
Joint Compression

The patient is positioned supine, with the clinician standing at the head of the bed. The clinician places the fingers of each hand under each side of the mandible, with the thumbs resting on the ramus. The mandible is then tipped posteriorly and inferiorly to compress the joint surfaces.

Medial-lateral

FIGURE 26-16 Contralateral protrusion and ipsilateral deviation force to TMJ.

Passive Articular Mobility Testing



The passive articular mobility tests assess the joint glides and the end-feels. The patient and clinician setup are identical to that described above for the temporomandibular (lateral) ligament stress test.

From the end-range position (or as close as possible, given that the thumb is in the patient's mouth), the following maneuvers are performed assessing for range and end-feel. Findings are compared with each side. Pain, or a restricted glide, are positive findings and may indicate articular involvement or a capsular restriction. It is important to check the specific glides that are related to the loss of active motion. For example, if a patient demonstrated diminished mouth opening, the combined anterior, inferior, and lateral glide is assessed at each joint.

Limited opening can be caused by anterior disk displacement without reduction, elevator muscle spasm, or capsular restraint. By inducing a passive stretch to the joint after the patient has actively opened the mouth to the full extent, the "end-feel" can be used to differentiate between these causes. For example, if a displaced disk is responsible for limited opening, there will be a hard end-feel with little or no play. In contrast, a gummy end-feel is present when muscle spasm or capsular connective tissue is preventing full opening.[56] Passive motions can be used to help differentiate between an elevator muscle spasm and a capsular restriction. With elevator muscle spasm, only the vertical movement is restricted, and protrusive and lateral excursions are normal. Anterior disk displacement without reduction, however, exhibits restrictions in both protrusive movements and contralateral excursions. The movement to the side of the involved joint is usually not mechanically restricted because the main movement occurring in the joint is a rotation. While hypomobility may be apparent with passive articular mobility testing, hypermobility is difficult to determine with these tests.

Most of the mobility tests can also be used for mobilizations by changing the grade and the intent. The clinician should remove the thumb from the patient's mouth every 10–15 seconds to allow the patient to swallow.

- Distraction (Fig. 26-14). The mandible is moved inferiorly in a direction perpendicular to the joint surface.
- Anterior glide (see Fig. 26-14). The mandible is moved anteriorly.
- Medial glide (see Fig. 26-17). The clinician stands to the side of the patient and stabilizes the patient's head. A medial force is applied by the other hand. This glide assesses the ability of the TMJ to side glide to the contralateral side from the side of the joint being tested.
- Posterior glide with a lateral excursion for the posterior ligaments.

Medial-lateral
(alternate position)

FIGURE 26-17 Medial glide.

Neurologic Tests

Trigeminal Nerve (Cn V)

Sensation. The skin near the midline (there is overlap from the anterior (ventral) rami of C2 and C3 if tested too laterally) of the forehead and face can be stroked with cotton wool or tissue paper or can be tested for pinprick sensation. It is best if the testing is carried out bilaterally and simultaneously.

Reflex. The jaw jerk can be used to test trigeminal function. A lesion superior to the pons would produce hyperreflexia, and a lesion below the pons would result in hyporeflexia or areflexia. The patient's mouth is relaxed and open in the resting position. The clinician places a thumb on the mandible and then lightly taps the thumb with the pointed end of a reflex hammer (Fig. 26-18). A normal response is one in which the mouth closes.

Facial Nerve (Cn VII)

The facial nerve can be tested using the Chvostek (Weiss sign) test. The patient is positioned sitting. The clinician taps the parotid gland overlying the mass of the muscle. If the facial muscles twitch (typically a twitch of the nose or lips), the test is considered positive for hypocalcemia (i.e., from hypoparathyroidism, pseudohypoparathyroidism, hypovitaminosis D) with resultant hyperexcitability of the nerves.

FIGURE 26-18 Jaw jerk test.

Special Tests

At the time of writing, no routine special tests for the TMJ exist. Most, if not all, of the structures of the TMJ, are isolated and tested during the standard examination previously described. Although cranial nerve testing (see Chapter 3) is not, strictly speaking, a special test, this testing should be performed if an injury to a cranial nerve is suspected. In addition, the special tests for thoracic outlet syndrome, brachial plexus stretching, and dural mobility should be performed to help rule out any referral of symptoms.

Imaging Studies

With the rapid progress made in TMJ imaging techniques, many studies have focused on the importance of internal derangement and osteoarthrosis as the underlying mechanisms in the etiology of TMJ-related pain and dysfunction. Despite the limitations, plain radiographs of the TMJ, such as high-level orthopantomograms and transcranial projections, are useful ways of visualizing any gross pathologic, degenerative, or traumatic changes in the bony component of the TMJ complex.[16,107] MRI is currently the most accurate imaging modality for identification of disk positions of the TMJ and may be regarded as the gold standard for disk position identification purposes.[108] However, many reports question the utility of TMJ imaging studies because of the number of asymptomatic individuals who demonstrate positive signs of disk displacements and joint arthrosis (degenerative processes affecting the TMJ).[4,109] Postmortem examinations of a total of 140 persons (dental histories unknown) showed that 40–80% had joint pathology or disk displacements.[109] T e relevance of bony joint arthrosis was also disputed by evidence that patients with TMJ rheumatoid arthritic pathology actually had fewer symptoms than normal individuals.[110]

In TERVEn TIOn STRATEGIES

T e lack of a consistent method for identifying and diagnosing TMD in a research setting, varying durations of treatment, lack of control groups, lack of objective-dependent measures, and lack of specification of symptom duration have prevented significant research on the effectiveness of various treatment modalities for TMD.[111] Complicating matters is the fact that the majority of the symptoms associated with TMD are self-limiting and resolve without active intervention.[49] T e chronic pain associated with TMD most likely occurs because of secondary factors. T ese factors include a fixed FHP, abnormal stress levels, depression, or oral parafunctional habits (such as bruxism). T is prolonged pain is frequently due to adaptive shortening of the tissues, or from a secondary hypermobility. It is likely that the longer the duration of the symptoms, the smaller the likelihood that the patient will benefit from a conservative intervention.[78]

In 2010, an interprofessional consortium revised the criteria to improve the reliability, validity, sensitivity, and specificity of the examination algorithms for TMDs, resulting in the diagnostic criteria/temporomandibular disorders (DC/TMD) (Table 26-9). T e DC/TMD provides a valid diagnostic classification based on the more common body structure/function impairments and activity limitations seen with TMD patients. T e DC/TMD describes two axes of focus for examination[112,113]:

- Axis I. T is encompasses a physical examination of body structure/functional impairments in the muscle and joint domains with diagnostic classifications as the outcome. T ree broad classification groups are contained: (1) Masticatory muscle disorders; (2) Joint disorders related to temporomandibular disk derangements (disk displacement with reduction, disk displacement without reduction); and (3) Joint disorders related to TMD arthropod arthritis, and arthrosis (Table 26-9).
- Axis II. T is focuses on identifying psychosocial characteristics that play a foundational or indictment in prior complaints.

A number of authors[114,115] have recommended that the intervention for TMD should be directed at the following factors[116]:

- Treatment of symptoms to reduce or eliminate the pain.
- Treatment of the underlying cause or the predisposing factor (poor posture, stress, depression, and oral parafunctional habits.[72,117]
- T e restoration of normal mandibular and cervical function.[70]

Recently, there has been an interest in the relative effectiveness of specific conservative interventions for TMD and, as a

TABLE 26-9 Diagnostic classification of physical conditions associated with TMD

Group I: Masticatory muscle disorders	Group II: Disc displacements	Group III: Joint dysfunction
Ia—with normal opening	IIa—disk displacement with reduction	IIIa—arthralgia
Ib—with limited opening	IIb—disk displacement without reduction with limited opening	IIIb—osteoarthritis
	IIc—disk displacement without reduction without limited opening	IIIb—osteoarthrosis

Data from Schiffman EL, Ohrbach R, Truelove EL, et al. The research diagnostic criteria for temporomandibular disorders. V: methods used to establish and validate revised axis I diagnostic algorithms. J Orofac Pain. 2010;24:63–78; Schiffman EL, Truelove EL, Ohrbach R, et al. The research diagnostic criteria for temporomandibular disorders. I: overview and methodology for assessment of validity. J Orofac Pain. 2010;24:7–24.

result, a number of systematic reviews have been performed in the area.[54,93,111,118–122] For example, Kulekcioglu et al.[120] reported that low-level laser therapy can be considered as an alternative physical modality in the management of TMD, and Tegelberg[123] and Au[124] have reported significant symptom reduction after exercise management of TMD. However, most of the studies have demonstrated the importance of a multifactorial approach to the conservative management of TMD. For example, the results of a systematic review by McNeely et al.[122] found manual therapy, and the use of active and passive oral exercises, and exercises to improve posture, as effective interventions to reduce symptoms associated with TMD. However, this review also found no evidence to support the use of electric physical modalities to reduce TMD pain.[122] A single case study by Cleland and Palmer[125] found manual physical therapy (anterior joint glides, distraction and contract–relax stretching to upper trapezius, levator scapulae, and posterior occipitals), therapeutic exercise (scapulothoracic muscles) and patient education with regards to posture, parafunctional habits, soft diet, tongue resting position, and activity modification to be an effective management strategy for a patient with bilateral disk displacement without reduction within eight visits.[125] Gatchel et al.[111] conducted a randomized clinical trial with a 1-year follow-up to evaluate the efficacy of a biopsychosocial intervention for patients who were at high risk of progressing from acute to chronic TMD-related pain. The study reported that the group who received behavioral skills training and biofeedback demonstrated reduced pain levels, improved coping abilities, and reduced emotional distress at the 1 year point.

It should be clear from the studies that TMD is complex and that there is a clear need for further well-designed RCTs examining physical therapy interventions for TMD, which include valid and reliable outcome measures.

Acute Phase

Acute injuries to the TMJ most frequently have a traumatic origin, such as a direct blow,[126–128] or from a sudden locking of the jaw caused by an internal derangement.[129,130]

The typical patient presentation for an acute injury demonstrates a capsular pattern of restriction (decreased ipsilateral opening and lateral deviation to the involved side), with pain and tenderness on the same side.

Physical Therapy

PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medications) are recommended during the acute phase, with the exception of elevation, which is neither appropriate nor feasible. Cold is applied to reduce edema, inflammation, and muscle spasm. Chapman[131] concluded that local application of cold provided short-term relief of pain, possibly because of its analgesic effects and ability to reduce inflammation. No single drug has been proved to be effective for all cases of TMD. Thus, a wide variety of drug classes have been described for chronic orofacial pain, ranging from short-term treatment with nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and muscle relaxants for pain of muscular origin to chronic administration of antidepressants for less well-characterized pain. The analgesic effect of NSAIDs is specific only in cases of TMD, in which pain is the result of an inflammatory process such as synovitis or myositis. At the doses usually prescribed clinically, opiates are more effective in dampening the patient's emotional response to pain than eliminating the pain itself.[132]

The patient should receive instruction on how to obtain the rest position of the TMJ.

The motion of the TMJ should be restricted to pain-free movements to allow the rest or immobilization of any painful muscular and articular structures. However, very gentle and pain-free active exercises should be frequently performed (every hour or so) to help stimulate the mechanoreceptors and modulate pain, as well as improve vascularization. Kropmans et al.[133] report that at least 6 mm of change has to be seen to be a detectable difference when doing more than one measurement or to determine the effect of treatment.

Appropriate exercises during the acute stage include the so-called 6 × 6 exercise protocol of Rocabado,[134] which are thought to aid in strengthening, coordination, and the reduction of muscle spasm. The patient should be instructed to perform the following exercises six times each at a frequency of six times per day.

- **Tongue rest position and nasal breathing.** The patient places the tip of the tongue on the roof of the mouth, just behind the front teeth. With the tongue in this position, the patient is asked to breathe through the nose and to use the diaphragm muscle for expiration only (no accessory breathing muscles).
- **Controlled opening.** The patient positions the tongue in the rest position and practices chewing and opening the mouth to the point where the tongue begins to leave the roof of the mouth. Another gentle exercise to help increase joint mobility and articulation is the "cork" exercise. The size (height) of the cork depends on the available motion. The patient holds the cork between his or her teeth while talking for approximately 2 minutes (Fig. 26-19). The talking exercise is then repeated with the cork removed.
- **Rhythmic stabilization.** The patient positions the tongue in the rest position and grasps the chin with one or both hands. The patient then applies a resistance sideways to

FIGURE 26-19 Cork exercise.

right deviation and then left deviation. The patient then applies a resistance against mouth opening and closing. Throughout all of these exercises, the patient must maintain the resting jaw position.

- The release of cervical flexion. The patient places both hands behind the neck and interlaces the fingers to stabilize the entire cervical region. The neck is kept upright while the patient performs craniovertebral flexion (see Chapter 23), which produces a distraction of the occiput from the atlas and helps to counteract the craniovertebral extension produced by the FHP.
- Longitudinal neck extension. The patient is asked to glide the neck backward and stretch the head upward in one movement to improve the functional and mechanical relationship of the head to the cervical spine. This exercise needs to be monitored closely to prevent hypermobility of the cervical segments.
- Shoulder retraction. The patient is asked to pull the shoulders back and downward in one motion while squeezing the shoulder blades together to help restore the shoulder girdle to an ideal postural position and to establish stability of the entire head–neck–shoulder complex.

Neuromuscular education techniques can be used to control premature or excessive translation. If premature translation has been found to be occurring, the patient is taught to maintain the tongue on the posterior portion of the palate and to monitor the lateral pole of the condyles during opening to ensure that only rotation occurs during the early phase of opening.[96]

One of the most commonly overlooked problems during TMJ intervention is altered swallowing sequence and tongue position.[96] Few other forces can match the ability of the tongue to cause occlusal and skeletal deformation.[135] The presence of a residual pediatric tongue thrust or an acquired adult tongue thrust secondary to a forward head posture can affect the response to all other interventions. The presence of a tongue thrust is manifested by the hyoid moving slowly up and down during swallowing, contraction of the suboccipitals during swallowing, or head rocking and excessive lip activity during swallowing.[96] Patients with these findings should be shown the normal resting position of the tongue, and swallowing should be practiced without movement of the head and with the correct sequencing of tongue movements.[135]

Patient Education

The clinician should explain the cause and nature of the disorder to the patient, and to reassure him or her of the benign nature of the condition.[117] A successful self-care program allows healing and prevents further injury and is often enough to control the problem.[136]

A typical self-care home program includes the following[117]:

- Limitation of mandibular function (rest). The patient is advised to eat soft foods and avoid those that need a lot of chewing and is discouraged from wide yawning, singing, chewing gum, and any other activities that would cause excessive jaw movement.
- An exercise program, including the 6 × 6 protocol.
- Habit awareness and modification.
- Stress avoidance. Patients should be advised to identify any source(s) of stress and to try to change their lifestyle accordingly.
- The patient's sleeping position. If the intrinsic ligaments are injured, the patient should be advised to sleep on the back, with the neck supported by a cervical pillow.[72] The prone position should be avoided as it compresses the TMJ and stresses the cervical spine by extending and rotating it.

Occlusal Appliance Therapy

The most common form of intervention provided by dentists for TMD is occlusal appliance therapy, alone or in combination with other interventions.[137] Occlusal appliances include bite-raising appliances, occlusal splints, or bite guards. These removable custom-made appliances are usually made of hard acrylic, which are custom-made to fit over the occlusal surfaces of the teeth in one arch.[117] The function of the occlusal device is to provide a stable jaw posture by creating single contacts for all of the posterior teeth in centric relation and centric occlusion.[137]

Although occlusal appliance therapy has been shown clinically to alleviate symptoms of TMD, the experimental evidence has been lacking, and thus the physiologic basis of the response to treatment has never been well understood.[138,139] Malocclusion, in itself, is not established as an important factor in TMD,[55,140] because very few patients with malocclusion actually go on to develop TMD.[141] In an evidence-based assessment of occlusal adjustment as a treatment for TMDs, Tsukiyama et al.[54] concluded that the experimental evidence reviewed was neither convincing nor powerful enough to support the performance of occlusal therapy as a general method for treating a nonacute TMD, bruxism, or a headache.[54]

Functional Phase

The interventions described for this phase are best used in combination and are dependent on the patient's needs.[4,78,142,143]

Postural Education

In a study of postural problems in 164 patients with head and neck pain, Fricton et al.[144] found poor sitting and standing posture in 96%, FHP in 84.7%, rounded shoulders in 82.3%, abnormal lordosis in 46.3%, and scoliosis in 15.9%. These findings indicate that there may be a correlation with TMJ dysfunction and poor posture, although comparisons would need to be made with a controlled group of normal individuals before final conclusions are drawn.

The focus of the postural intervention should be to educate the patient on the correct posture of the head, neck, shoulder, and tongue, in order to help minimize symptoms. Oftentimes, the focus of the education is to teach the patient mental reminders to reduce the times spent in habitual positions during work and recreation. These positions, which cause an alteration in the tensile properties of

the muscles and adaptive shortening of the joint capsule and ligaments, result in a variety of problems, including joint strain and improper weight bearing through the joint.[145–147] The pathologic posture then becomes associated with, or the precursor of, other deformities. A balanced and relaxed position, on the other hand, affords the best mechanical advantage for the body.[137] Since these postural deviations do not always cause symptoms,[148] and the corrected positions require effort to maintain, patients need reassurance that the benefits in changing their posture may take time.[98,149]

Psychotherapy

Researchers in orofacial pain acknowledged the importance of the psychological domain in causing and/or maintaining pain, and in regulating peripheral and central neural structures involved in nociception. Some studies suggest that, on occasion, TMD may be the somatic expression of an underlying psychological or psychiatric disorder such as depression.[150,151] These studies have demonstrated increased psychometric scores denoting pain, chronic disability, and depression in TMD patients that far exceed the general population. A study by Gardea et al.[152] evaluated the relative long-term efficacy of electromyographic biofeedback, CBST, combined biofeedback and CBST, and no treatment in 108 patients suffering from chronic TMD. After an initial evaluation, patients were assigned to one of the four treatment groups. The three biobehavioral interventions consisted of 12 standardized sessions. Patients were reevaluated 1 year after completing treatment. Results demonstrated that patients who received the biobehavioral interventions reported significant improvement in subjective pain, pain-related disability, and mandibular functioning 1 year after receiving the treatment. The no-treatment comparison group did not demonstrate such improvements, whereas the combined biofeedback and CBST treatment produced the most comprehensive improvements in all outcome measures.

Where persistent habits exacerbate or maintain the TMD, a more structured program of behavioral therapy may be required. Such behavioral therapy may include counseling on lifestyle, relaxation therapy, sleep interruption devices, or hypnosis.[2] Medical hypnosis has been demonstrated to be an effective treatment modality for TMD, in terms of reducing both symptoms and medical use.[153]

Manual Therapy

The specific manual techniques for the TMJ are described under "Therapeutic Techniques" section later.

Trigger Point Therapy

One of the most common intervention for masticatory muscle disorders is trigger point therapy.[2] Chapter 11 reviews the basis for the various intervention procedures for trigger points, which include deep massage, soft-tissue mobilizations, postural exercises, ultrasound, acupuncture, and trigger point injections. Spray and stretch techniques may also be used. These techniques involve the application of a vapocoolant spray during the stretching of soft tissues to reduce trigger points and eliminate referred pain. Vapocoolants may also be applied to cool the skin and overlying musculature rapidly during stretching. When using vapocoolants in this region, care must be taken to cover the patient's eyes and to prevent any inhalation of the vapors.

Exercise

Some evidence suggests that exercise of the specific painful area during the functional phase is effective in strengthening the muscles, improving function, and reducing pain.[2]

Because of the association of TMD and poor posture, the prescribed exercises for TMD include strengthening exercises for the cervicothoracic stabilizers (see Chapter 25) and the scapular stabilizers (see Chapter 16). Stretching exercises are prescribed for the scalenes, trapezius, pectoralis minor, and levator scapulae (see Chapter 25) and the suboccipital extensors (see Chapter 23).

A restriction of mouth opening is treated with ROM exercises to elongate the soft tissues and with joint mobilizations. The patient should be encouraged to begin full AROm exercises as early as tolerated (see the discussion of automobilizations under "Therapeutic Techniques" section later). However, if jaw deviation is occurring, the exercises should be performed in a range in which the patient can control the deviation.

Excessive mandibular motion is treated by muscle reeducation, with isometrics performed at the desired opening range.

Thermal and Electrotherapeutic Modalities

A multitude of electrotherapeutic modalities, especially ultrasound, and electrical stimulation, have been applied to patients with TMDs, but there appears to be little evidence that passive modalities alone can cause long-lasting reductions, and very few studies have systematically evaluated the effect of these treatments.[2]

Moist Heat Packs. Conventional hot packs or face packs may be used in the functional stage and are applied for approximately 15 minutes. Thermotherapy is used to help the soft tissues relax and to increase circulation.

High-Voltage Electric Stimulation. High-voltage stimulators deliver a monophasic, twin-peak waveform. Because of the short duration of this twin-peak wave, high voltages with high-peak current but low average current can be achieved. These electrical characteristics provide patient comfort and safety in the application. In addition, in contrast to low-voltage direct-current devices, thermal and galvanic effects are minimized.

High-voltage stimulators can be applied clinically to reduce or eliminate muscle spasm and soft-tissue edema, as well as for muscle reeducation (non–CNS-produced muscle contraction), trigger point therapy, and increasing blood flow to tissues with decreased circulation.[81]

Ultrasound. The effects of ultrasound are partly thermal, because of the increase in blood flow and tissue temperature produced. Thus, ultrasound may be used to help the soft tissues relax and to increase circulation. Ultrasound is an ideal modality both before and during joint and soft-tissue mobilization. There is also a mechanical effect associated with ultrasound because the sound waves produce pressure changes in the tissues, which may result in a micromassage of the tissues. A 3-MHz frequency is recommended, with an intensity between

0.75 and 1.0 W/cm^2. Tongue depressors can be inserted in the patient's mouth to apply a gentle stretch during the ultrasound treatment.

Iontophoresis. Iontophoresis may be used to introduce medications such as cortisol, dexamethasone, salicylates, and analgesics.

Surgical Intervention

A range of surgical procedures is currently used to treat TMD, ranging from TMJ arthrocentesis and arthroscopy to the more complex open joint surgical procedures, referred to as arthrotomy.[9]

The proximity of the medial aspect of the TMJ to the structures of the infratemporal fossa raises the possibility of complications associated with TMJ surgery on the medial aspect of the joint. These complications include involvement of the inferior alveolar, lingual, and auriculotemporal nerves.[154] A further study found that the location of such vital structures as the middle meningeal artery, the carotid artery, the internal jugular vein, and the trigeminal nerve varied, increasing the likelihood of significant intraoperative or postoperative complications.[155]

In terms of intervention, the postsurgical patient is treated as though in the acute phase of healing and is progressed gradually, as outlined under "Intervention Strategies" section earlier.

PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Internal Derangement: Intraarticular Disk Displacement

Impairments of the TMJ may involve the temporomandibular disk, joint surfaces, joint capsule, or synovium, or any combination of these structures. The DC/TMD categories of group II (disk displacement) and group III (joint dysfunction) are integrated here, because disk disorders become problematic for patients primarily when these result in joint pain (arthralgia) or functional motion restrictions.[70] TMJ internal derangement is one of the most common forms of TMD and is associated with characteristic clinical findings such as pain, joint sounds, and irregular or deviating jaw function. The term internal derangement when related to TMD denotes an abnormal positional relationship of the articular disk to the mandibular condyle and the articular eminence. This abnormal positional relationship may result in mechanical interference and restriction of the normal range of mandibular activity. Theoretically, internal derangement of the TMJ involves the anterior (and medial) displacement of the disk, resulting from the action of the upper head of the lateral pterygoid muscle, a tear or thinning of the disk, osteoarthrosis, or malocclusion.[156] Macrotrauma, as may occur from opening the mouth for dental procedures, intubations, and blows to the face, can result in plastic deformation and injury to the retrodiskal tissue and/or the collateral ligaments that anchor the disk to the condyle.[70] Alternately, repeated microtrauma, as occurs with parafunctional activities of gritting, grinding, and bruxism, can cause excessive force on the disk, resulting in disk thinning or perforations and disk displacement.[70]

Disk Incoordination

Disk incoordination may occur when the intraarticular disk adheres to the eminence that usually occurs after a prolonged period of TMJ inactivity, such as that occurs with postsurgical immobilization. Other causes of this condition include occlusion, bruxism, excessive biting force, and trauma. The adhesion can result in a loss of the translatory glide of the condyle, which in turn can result in excessive pressure between the disk and the eminence and a strain on the diskal ligaments, predisposing the patient to a true disk displacement of the joint.

Clinical findings with this condition may include a discrete opening click with momentary discomfort while the remainder of the translatory cycle is accomplished without difficulty.[157] The click associated with a deviation in the form usually occurs at the same point in the range of opening and closing.

The conservative intervention for this condition should focus on the elimination of any occlusal disharmony, the reduction of parafunctional habits, and methods to prevent the disk–condyle complex from returning to the closed position.[8] The latter goal can be accomplished by applying a permanent stabilization splint for a few months. When symptoms have been reduced, the patient should be weaned from the splint during the day and, eventually, night.

Articular Surface Defects

An articular surface defect located on the articulating surface of the eminence, the superior surface of the disk, or both, may cause an obstruction to the normal translatory movement of the disk.[158] The defect may be caused by trauma to the mandible when the teeth are apart, habitual abuse, or developmental and growth anomalies.[8]

Clinical findings for articular surface defects include a reciprocal click at the same point during both opening and closing movements. In addition, a lateral deviation frequently occurs on opening, as the patient attempts to circumvent the interference. Although the condition itself is painless, it can be worsened by any activities that increase intraarticular pressure.[8,81]

Conservative intervention for this condition includes habit training to develop a path of mandibular movement that avoids the interference. In addition, the patient is asked to make a conscious effort to reduce the force of chewing and eliminate parafunctional habits. Chewing on the affected side, by decreasing the intraarticular pressure, may also be helpful. A stabilization splint may serve to reduce pressure on the joint structures.[8,157]

Disk Thinning and Perforation

Disk thinning can result from the application of excessive pressure on the TMJ and can lead to a deformation of the joint structures. The continuous pressure eventually may cause perforation of the disk.

The symptoms of disk thinning and perforation depend on the extent of disk damage. Theoretically, thinning of the central part of the disk should be painless because that part of the disk is not innervated. However, variable joint tenderness and muscle pain often is associated with any activity that deepens the central bearing area of the disk.

If the disk should perforate, grating sounds or crepitus during the translatory cycle are likely because of damage to the articular surfaces.[159,160] The diagnosis of disk perforation usually is made by imaging, arthrography, or arthroscopy. MRI, which is ideal for visualizing disk displacement, may not be so accurate for a perforation.[161]

Conservative intervention for disk thinning usually involves the application of a stabilization splint to prevent a perforation. If perforation has occurred, and the patient can no longer tolerate the symptoms, surgical intervention is indicated.

Disk Displacements

Anterior disk displacement is the most common type of disk displacement.[81] A pathologic click in a disk displacement occurs when the condyle glides onto the middle aspect of the displaced disk later than normal in the opening cycle. A reciprocal click, sometimes muted, occurs during mouth closing as the condyle slips posteriorly on the anteriorly displaced disk, or it may represent the sudden snapping back of the disk by the less than adequately elastic posterior ligament of the disk.

Partial Anteromedial Disk Displacement

In a healthy joint, the center of the posterior band of the disk is in the 12 o'clock position on the condyle when the teeth are occluded. With partial anterior disk displacement, the disk is permitted to slide anteriorly on the condyle and the terminal position of the posterior band of the disk occurs anteriorly to its normal position on the condyle in the closed-joint position. The anterior displacement is thought to occur because of two factors: some thinning of the posterior band and minimal elongation of the diskal ligaments.[157]

The conservative intervention for partial displacements should focus on preventing any worsening of the disk displacement. This can be achieved using intraoral appliances in combination with psychological stress reduction.

Anteromedial Intraarticular Disk Displacement with Reduction

Disk displacement with reduction is both an anatomic and functional disorder that is cyclic in nature.[161] Anteromedial disk displacement with reduction is described as an unexpected alteration or interference of the disk–condyle structural relation during mandibular translation with mouth opening and closing.[70] The misalignment of the disk is thought to be the result of articular surface irregularity, disk–articular surface adherence, synovial fluid degradation, or myofascial imbalances around the joint.[81]

The temporarily misaligned disk reduces or improves its structural relationship with the condyle when mandibular translation occurs with mouth opening. This change often is associated with an "opening click," and a reciprocal "closing click," which occurs just before the teeth occlude during mouth closing. Pain, if present, usually occurs at the time of the disk reduction.

Disk displacement with reduction may be characterized by five progressive stages.[72,81]

- Stage I. In stage I, the disk may be positioned slightly anteromedially on the mandibular head. Pain is usually mild or absent. As the disk becomes deformed from the repetitive microtrauma, it begins to interfere with the normal translation of the condyle.
- Stage II. In this stage, the disk slips further anteromedially on the mandibular head. The reciprocal click may occur in the early phase of opening and late in the phase of closing. Stage II is characterized by a loss of integrity of the ligamentous and intracapsular structures. This loss of integrity may result in increased mobility and a decrease in control of the disk, which increases the potential for impingement and deformation of the disk, resulting in severe pain, and increases the potential for intermittent open locking or subluxation of the joint. An open lock is characterized by two opening clicks, and two clicks on closing. During opening, the first click occurs when the condyle moves over the posterior rim of the disk and the second click as the condyle moves over the anterior rim. If, after the second click occurs on opening, the disk lies posterior to the condyle, the condyle may be prevented from sliding back.
- Stage III. Stage III, often the most painful stage, is characterized by a reciprocal click that occurs later in the opening cycle and earlier in the closing cycle. Occasionally, the intraarticular disk becomes adherent to the mandibular condyles in both the open and closed positions. This is known as a closed-lock position. The sustained closed-lock condition produces a sudden limitation of opening, as the disk becomes permanently lodged anteriorly, thereby interfering with the normal condylar rotation and translation.[162] This closed-lock condition results in a hard end-feel in the joint when the clinician attempts to induce a passive stretch to the joint. The impingement on the posterior attachment of the disk by the condylar head may result in a prolonged stretching of the tissue. The limitation of opening usually is restricted to 25–30 mm. Since condylar translatory mobility commonly is hindered only on the affected side, the mandible may deviate away from the midline toward the affected side with maximal jaw opening. However, if this condition is chronic, there may be no deviation or limitation of jaw opening because of progressive tearing in the retrodiskal lamina. Tenderness of the masticatory muscles may also occur as a result of the protective splinting of the joint.
- Stage IV. In this stage, clicking is rare because the disk position is usually so incompatible. If clicking does occur, it is usually a single opening click because of the irregularities in translations.[72] Chronic locking with soft-tissue remodeling can occur as a result of routine daily jaw function on the posteriorly or anteriorly positioned disk. [162] Known as rotational displacement, this condition is associated with pain and, commonly, with anterior displacement of the disk.

- Stage V. This stage is characterized by radiographic degenerative changes on the condylar head and, occasionally, on the articular eminences, with evidence of remodeling and osteophytosis.[161] Marked deformity and thickening of the disk may occur, and the shape of the disk may change in configuration from biconcave to biconvex. The joint space typically is narrowed to the point where bone-on-bone contact is evident, resulting in coarse crepitus with jaw motions.

Stages I and II usually are amenable to physical therapy intervention. The focus for these stages is on reducing muscle dysfunction and improving the biomechanics of the joint. The intervention usually involves using mandibular-repositioning appliances that stabilize a protrusive position to keep the disk in a more optimal relationship with the condyle. The primary purpose of protrusive splint therapy may be to allow repair and regeneration to occur in the retrodiskal tissue and, possibly, in the diskal ligaments.

The intervention for stages III–V, and for those patients who are postsurgical, is directed at promoting and progressing the healing, restoring joint ROM, and reducing the inflammation associated with capsulitis.[162]

Anteromedial Disk Displacement with Intermittent Locking

As mentioned in the previous section, if the disk remains displaced for longer periods of time, its shape becomes deformed and may slowly change from biconcave to biconvex. This change in shape makes the passage of the condyle under the disk more difficult. To return the disk, the patient must learn to move the mandible to the opposite side in order to activate the superior retrodiskal lamina. Unfortunately, at this point, the retrodiskal tissue has thinned considerably and lost much of its elasticity, making disk reduction difficult to achieve.

The intermittent locking may occur at any time, but it most often occurs in the morning upon awakening, after a prolonged period of clenching, or after chewing on the involved side.[90] Conservative intervention usually involves a mandibular-repositioning appliance to keep the disk in correct alignment with the condyle.

Intraarticular Disk Displacement Without Reduction

Although some patients may show progression through the various stages of disk displacement, it is unclear why some patients remain in the category of anterior disk displacement with reduction for years, whereas others proceed to intermittent locking and anterior disk displacement without reduction within a matter of months.

Disk displacement without reduction is described as an alteration or interference of the disk–condyle structural relation that is maintained during mandibular translation. As a result of continued disk deformation along with elongation of diskal ligaments and a loss of tension in the posterior attachment, the disk may remain anteromedially displaced creating a "closed lock."[81] Contact is lost among the condyle, disk, and articular eminence, and the articular disk space collapses, trapping the disk in front of the condyle and thereby preventing translation. Usually, the displacement of the disk becomes worse with jaw motions. Initially, there may be an associated locking with a sudden and marked limited jaw motion. In addition, there may be a deviation of the mandible toward the involved side during mouth opening, and a marked limitation of lateral deviation to the contralateral side.

The limited opening resulting from anterior disk displacement without reduction may have a variety of causes. In addition to the more common causes, including muscle spasm and capsular tightness, limited mouth opening may occur when either the disk is lodged anteriorly to the condyle or the TMJ is dislocated or subluxed. Limited mouth opening as a result of elevator muscle spasm or capsular restraint can be differentiated by determining the end-feel. Elevator muscle spasm tends to limit only vertical movement; the protrusive and lateral excursions are usually normal. Anterior disk displacement without reduction, however, exhibits restrictions in both protrusive movements and contralateral excursions. The movement to the side of the involved joint is usually not mechanically restricted because the main movement occurring in the joint is a rotation. Pain restriction may be the result of impingement on inflamed retrodiskal tissues. Secondary muscle spasm of the elevator muscles may add to the restricted opening as well as capsular involvement.

In the acute phase, joint noise is usually absent. However, crepitus may be detected as the displacement becomes chronic, and changes occur on the articular surfaces. As the condition becomes chronic, the pain often is markedly reduced, and the ROM may approach normal dimensions.

The intervention for the acute phase of this type of disk displacement should focus on a reduction of the displaced disk through mobilization of the joint. Since secondary elevator muscle spasm is usually present, as well as some inflammation of joint structures, it may be of benefit for the patient to take a skeletal muscle relaxant and an NSAID prior to physical therapy session. The reduction procedure involves the patient opening the mouth as wide as he/she is comfortable and then moving the mandible toward the opposite joint. If unsuccessful, the clinician may then attempt to reduce the disk manually through downward pressure on the last molar on the involved side.[81] Success in reducing the disk usually can be clinically determined by comparing the amount of vertical opening and contralateral movement after mobilization with the amount of movement before mobilization. This difference should be verified through imaging because clinical criteria alone may not be accurate. Generally speaking, reductive mobilization is more successful in the more acute conditions. In cases in which changes in the connective tissue capsule may be contributing factors, manual stretching of the vertical fibers of the capsule may be indicated.

Adhesive Disk

Although many cases of intracapsular restriction of mandibular movement or closed lock are caused by an anterior disk displacement without reduction, another frequent abnormality of the TMJ is the formation of intraarticular adhesions. The restriction may also be caused by an adhesion occurring

in the superior joint cavity between the disk and the eminence, resulting in a loss of condylar translation. In addition, an adhesion may result in condylar displacement of the disk, with distortion of the disk itself on mandibular opening.[161]

Trauma frequently is implicated as a causative factor. If the trauma is slight, only mild surface damage to the disk may occur, resulting in disk incoordination or an articulating surface defect. A more severe episode could cause intracapsular bleeding and effusion. Fibrosis may result, producing a reduction in the ROM as well as degeneration. T e condylar translation may be lost as a result of disk adhesion.

Clinically, adhesive disk hypomobility is indistinguishable from acute anterior disk displacement without reduction. Since translation does not occur, opening is limited. Pain is variable and may be caused by stretching of the diskal ligaments, as forced opening is attempted.

T e conservative intervention for adhesive disk hypomobility is specific joint mobilizations (see "T erapeutic Techniques" section later).

Displacement of the Disk–Condyle Complex

Subluxation[163]

Subluxation between the disk and the articular eminence may occur as a result of excessive opening, which can force the condyle and the disk anteriorly beyond the normal limits of the translatory cycle. If the disk cannot rotate any farther posteriorly, and the condyle continues to translate, a partial dislocation or subluxation can occur.

Usually, the patient has a history of jaw clicking with wide mouth opening. Diagnostically, for treatment purposes, this wide opening click must be differentiated from a click that signifies reduction of a displaced disk. A subluxation type of click occurs only on wide opening and not on protrusive movement or lateral excursion. T e click associated with a reduction of a displaced disk, however, can occur during both protrusive and contralateral excursion. Usually, pain does not accompany subluxation unless it becomes habitual.

Intervention for this condition includes habit training to limit mouth opening voluntarily within normal limits. T is training should be accompanied by exercises that strengthen the elevator muscles. Occasionally, injection of a sclerosing solution to reduce the laxity of the capsule may be required.

Dislocation[163]

Dislocation of the TMJ is caused by additional rotation of the mandibular condyle beyond its biomechanical limit, resulting in an anterior displacement of the disk beyond the articular eminence and in direct contact between the condyle and the eminence. As opposed to subluxation, which is a partial loss of contact between the disk and the eminence, dislocation involves a collapse of the articular disk space. Because of the collapsed disk space, the superior retrodiskal lamina cannot retract the prolapsed disk. Adding to the problem is the elevator muscle spasm that frequently accompanies dislocation and preserves the decrease in articular disk space.

Some factors associated with the onset of habitual dislocation include, but are not limited to, yawning, singing, sleeping with the head resting on the forearm, manipulation of the mandible while the patient is under general anesthesia, excessive tooth abrasion, severe malocclusion, loss of dentition (leading to overclosure), and trauma.[164]

Clinical findings include an inability of the patient to close the mandible after wide mouth opening so that the mouth becomes locked open in a prognathic position and cannot be moved vertically. An acute malocclusion is present with an anterior open bite and contact between only the most posterior teeth. Depressions may be noted in the preauricular area formerly occupied by the condyles. Pain may be variable, which increases as the patient attempts to close, thus straining the inferior retrodiskal lamina and the collateral diskal ligaments.

T e main focus of the intervention is to widen the articular disk space. T is allows the superior retrodiskal lamina to retract the disk. Forceful closing of the mandible should be avoided. Reduction of the displaced mandible is best accomplished by having the patient yawn as widely as possible while the clinician exerts slight posterior pressure on the chin. If the reduction is not achieved, placement of thumbs behind the molars and pressing down while the patient yawns may produce the reduction by increasing the additional articular space. If these attempts at manual correction fail, the clinician may try stimulation of the gag reflex by touching a mouth mirror to the soft palate. T is maneuver can result in an inhibition of elevator muscle activity, thus increasing the articular disk space.

For recurrent dislocations, the conservative approach is addressed according to the stability factors into (1) alteration of the ligaments, (2) alteration of the associated musculature, and (3) alteration of the bony anatomy[164]:

- Alteration to the ligaments can be achieved by the introduction of a sclerosing agent into the capsular space of the TMJ.
- Alteration of the associated musculature can be achieved by exercise. Strengthening the suprahyoid muscles to counterbalance the action of the lateral pterygoid muscles could, theoretically, reduce the likelihood of dislocation. T e equipment to perform this type of exercise, however, is elaborate and involves considerable compliance by the patient. A more recently reported treatment modality for alteration of the musculature is the use of type A botulinum toxin. If the dislocation is chronic, the patient should be taught how to self-reduce the mandible. Habit training similar to that employed for subluxation should be instituted.
- An alteration of bony anatomy requires a surgical eminectomy.

Arthritis

T e TMJ, like other joints in the body, can become a site of osteoarthritis. Osteoarthritis and osteoarthrosis represent degeneration of the articular surface of the TMJ, with the former being associated with inflammatory processes. Degenerative osteoarthritis may be secondary to excessive loading, prolonged chemical irritation (i.e., inflammation), trauma, surgery, congenital malformation, or, most commonly, long-standing disk derangement. Marginal osteophyte formation, bony erosion sclerosis, and the subchondral or subcortical formation may be observed.[161] T e temporomandibular disk

may become distorted in shape secondary to adhesions seen in osteoarthritis.[81]

Other arthritides are known to affect the TMJ, including rheumatoid arthritis, systemic lupus erythematosus, synovial chondromatosis, ankylosing spondylitis, psoriasis, and crystalline arthritides such as calcium pyrophosphate deposition disease and gout.

The patient may report joint pain and crepitus or a grating feeling throughout the entire joint movement.[70] To date, no intervention exists that can reverse the anatomic and biochemical alterations of osteoarthrosis. Thus, the intervention approach has to be aimed at restoring function and managing pain through the acute phase of the disease.

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis (PVNS) is a proliferative but nonneoplastic disorder of unknown pathogenesis that affects the synovial membranes of joints.[165] Eighty percent of cases involve the knee, followed in order of frequency by the hip, ankle, and shoulder, with the involvement of the TMJ being very rare.[166] The disorder is generally thought to be a benign, inflammatory process, although it may develop as an aggressive local process.

PVNS is described as expressing multiple manifestations of a histologic lesion occurring in the synovial membrane of joints. PVNS is subdivided into diffuse and localized forms, depending on the extent of synovial involvement. PVNS may extend into bone, and, in most instances, the diffuse form probably represents aggressive extraarticular extension and occasional recurrence after surgical intervention.[166]

The symptoms of PVNS of the TMJ vary but typically include swelling in the preauricular area, progressive TMJ pain during mastication, and a history of progressive difficulty in opening of the mouth.[165]

The recommended intervention for PVNS lesions involves synovectomy at all sites involved.[166]

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Masticatory Muscle Disorders

The masticatory muscles include the lateral pterygoid, the temporalis, and the medial pterygoid. Masticatory muscles may be directly injured through overuse and/or tensile strain, and indirectly through muscle guarding and centrally mediated myalgia.[70] Such dysfunctions include trauma, occlusal imbalance, changes in the vertical dimensions between the teeth, immobilization, prolonged dental procedures, chronic teeth clenching, and disease. Centrally mediated myalgia is a process that involves chronic overactivation of muscle, as a result of central sensitization (see Chapter 3).[167] Schwartz[168,169] hypothesized that TMD symptoms originated in mandibular muscles, which went through three pathologic phases:

- Early incoordination of muscles, producing joint clicking and recurrent subluxation.
- A middle phase of limitation of mandibular movements by muscle spasm.
- A final phase of muscle shortening and fibrosis, often irreversible. Psychogenic causes were the most common.

The role of cervical whiplash injuries secondary to motor vehicle accidents (MVAs) in TMD is somewhat controversial. Brooke and Stenn[170] reported that patients with posttraumatic TMD had a poor prognosis for recovery compared with nontraumatic TMD, stating as reasons the consequence of litigation and the personality of the patient. It seems plausible that an injury to the suprahyoid and infrahyoid muscles would affect the function of the mandible, thereby predisposing the joint to dysfunction. Mechanisms have been proposed to explain how an MVA trauma could cause TMDs.[171,172]

During the initial backward movement, the jaw is forced open, stretching and possibly tearing the anterior joint capsule and the intraarticular disk. On the flexion phase, the jaw is snapped shut by the stretch reflex of the masticatory muscles and, in the presence of malocclusion, damages the posterior and temporal attachments of the articular cartilage and disk.

The following descriptions outline the common referral patterns of the TMJ muscles.

Temporalis

Referred pain from the temporalis muscle may extend over the temporal region, to the eyebrow and the upper teeth, and to the maxilla and TMJ.[102] A headache caused by temporalis muscle spasm is common. The patient also may feel pressure behind the eye or have increased eye fatigue.

Lateral Pterygoid

Spasm of the lateral pterygoid may cause a deep ache in the cheek area, maxilla, TMJ, or ear. Pain also is felt with chewing.

Medial Pterygoid

The medial pterygoid may refer pain behind the TMJ, deep in the ear, to the tongue, and to the back of the mouth.[102]

Masseter

Referred pain from a masseter muscle spasm may be projected to the eyebrow, maxilla, anterior mandible, and upper and lower molars.[102] The intervention for these muscle spasms includes:

- application of moist heat to promote muscle relaxation;
- massage of the affected muscles;
- passive and active self-stretch exercises; and
- spray and stretch techniques.

Forced mouth opening should be avoided. In the absence of joint hypomobility, yawning exercises are recommended as a home exercise, because this activity produces a strong reflex inhibition of the mandibular elevators.[102]

The lateral pterygoid can be passively stretched with maximal retrusion, followed by rhythmic sideways oscillations.

The medial pterygoid can be passively stretched with jaw-opening exercises.

Simons et al.[102] recommend the use of the mandibular self-stretch exercise for the temporalis and masseter muscles.

The exercise, which consists of three steps, is performed in the sitting position:

- Hot packs are applied to both sides of the face.
- The index and middle fingers are inserted below the lower incisor teeth, pads facing downward. The thumb of the same hand grasps the chin and pulls the lower jaw forward.
- The full stretch is achieved by pulling the jaw downward while continuing to pull it forward.

Synovitis

Synovitis of the TMJ occurs when the internal lining of the joint capsule becomes inflamed, resulting in a palpable tenderness of the posterior and lateral aspects of the joint. The cause of the synovitis can be[31]

- condylar impingement of the loose areolar connective tissue located immediately posterior to the condyle, which can result in significant effusion;
- systemic disease, such as osteoarthritis, or rheumatoid arthritis or its variants; and
- infection, particularly viral.

INTEGRATION OF PRACTICE PATTERNS 4B, 4C, AND 4F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE AND RANGE OF MOTION SECONDARY TO IMPAIRED POSTURE, SYSTEMIC DYSFUNCTION (REFERRED PAIN SYNDROMES), SPINAL DISORDERS, AND MYOFASCIAL PAIN DYSFUNCTION

Cervical Spine Disorders

Patients with TMD frequently report symptoms related to cervical spine disorders, and vice versa.[97,173–175] Several authors have indicated the existence of neuroanatomic and biomechanical relationships and have suggested that a dysfunction of the cervical spine may be the cause of signs and symptoms in the head.[176–187]

The masticatory and cervical muscles can affect the rest position of the mandible, the mechanism of mandibular closure, and the occlusion.[188–190] Thus, a change in the rest position of the mandible or habitual cervical posture can affect the occlusion and the masticatory muscles.[63,188,191–193] The most common postural abnormality in the cervical spine with direct impact on the craniofacial area and temporomandibular arthralgia is the forward head posture.[63,188,191–193]

Any increase in the sternocleidomastoid angulation, or distance from the thoracic apex to the midcervical region, constitutes an FHP. This posture is considered to be minimal at 60 degrees, moderate at 60–75 degrees, and maximal at 75–90 degrees.[17] Associated signs include a decrease or reversal in the cervical lordosis and an increase in cranial rotation at the occipitoatlantal joint, resulting in a shortening and excessive activity of the posterior cervical muscles. The FHP can place undue stress on both the posterior cervical muscles and the anterior submandibular muscles, by increasing their normal resting lengths. This stress may also stretch the TMJ capsule and alter the bite biomechanics of the TMJ, resulting in a posterior migration of the mandible and an altered occlusal contact pattern.

Atypical Facial Pain

Atypical facial pain is characterized by typically unilateral, dull, and relatively constant facial pain, and the presence of tender points. This condition recently reclassified as facial pain by the International Headache Society, is not well understood and often defies all modes of intervention.[194] Many authorities believe that atypical facial pain is psychogenic.[195,196] However, it has been reported that intraoral edema and trigeminal V2 nerve distribution area tenderness were consistently found in individuals with atypical facial pain.[197] Furthermore, these individuals experienced relief of their symptoms in response to low-level helium–neon laser therapy.[197]

Bell's palsy, a common form of facial paralysis, and Ramsey Hunt syndrome, a herpetic inflammation of the geniculate or facial nerve ganglia, are described in Chapter 5.

Trigeminal neuralgia

Trigeminal neuralgia is an intensely painful disorder of the face of brief duration (30 seconds).[198] The pain is spontaneous and can be triggered by touch, cold, shaving, brushing teeth, or make-up application.[199] The cause of trigeminal neuralgia is at present unknown, although most authors place the site of disturbance in the region of the posterior root[200,201] or in the spinal tract of the nerve.[202] Injuries to nerves and soft and hard tissues as a result of repeated traumas have been reported to produce persistent pain because of sensitization of both peripheral and central neurons.[49,203] The sensitization process has been shown to influence subsequent pain experience. Increased postoperative pain resulting from insufficient preemptive analgesia, such as incomplete use of local anesthetics or pain medication before surgery, has been well documented.[203–205] Poorly managed postoperative or posttraumatic pain also is considered to play a role in pain persistence.[203,206]

Myofascial Pain and Dysfunction

Many clinicians over the years have described numerous conditions that share features such as fatigue, pain, and other symptoms in the absence of objective findings. These include illnesses such as chronic fatigue syndrome, fibromyalgia, and TMD.

Myofascial pain and dysfunction associated with TMD generally present with diffuse pain that is cyclic and found in several sites in the head and neck, particularly the muscles of mastication.[16] Pain is frequently at its worst in the morning,

the patient often reports sore teeth from clenching, and there is often a history of stress and difficulty sleeping.[16] Masticatory muscle pain associated with TMD does not appear to progress in severity with age.[207]

The intervention for myofascial pain syndromes requires a comprehensive, and often a multidisciplinary, approach. The role of physical therapy in these syndromes is one of patient education, manual therapy techniques and electrotherapeutic modalities to reduce pain, and exercises to improve posture, reduce the adaptive shortening of tissues, and improve the strength of the postural stabilizers.

THERAPEUTIC TECHNIQUES

Manual Therapy

The aim of manual therapy in TMD is to restore normal mandibular function using a number of techniques that serve to relieve musculoskeletal pain and promote healing of tissues.[208]

In the acute phase, manual techniques, if used at all, should be very low grade and very carefully performed, because this joint tends to be very reactive and can flare up easily. To reduce hypomobility and acute locking of the TMJ, mobilization and massage can be applied to the TMJ, as well as to the muscles of mastication to stretch and relax them.[162]

Muscle relaxation and soft-tissue techniques often are required before mobilizations of the TMJ can be performed.

Myofascial Release

Myofascial release is a combination of direct, indirect, and reflex neural release procedures.[96] The basis of this technique is sensing palpable changes at various tissue levels and manually directing a gentle force to assist in releasing restricted tissues.

Muscle Stretching

Muscle stretching techniques can be used if the examination shows that the restriction of movement is a result of shortened muscles (or other structures). Techniques to increase the extensibility of the cervical structures are described in Chapters 23 and 25.

Joint Mobilizations

Specific joint mobilizations of the craniovertebral and cervical regions are described in Chapters 23 and 25, respectively. Specific mobilization techniques of the TMJ are indicated for decreased ROM and pain caused by muscle contracture, disk displacement without reduction, and fibrous adhesions in the joint.[72]

During these procedures, the patient's mandible should be completely relaxed, and the patient should not attempt to open his or her mouth until instructed to do so.

Techniques to Increase Mouth Opening[56,209]

Distraction

This technique is performed to separate the joint surfaces of the TMJ to allow the disk to start repositioning on the condyle and to start realigning the fibers of the tissue caudally. The patient is positioned sitting, and the clinician stands to the patient's side. The clinician grips the patient's head, using his or her forearm and hand, fingers against the patient's forehead. The clinician stabilizes the patient's head with his or her hand, arm, and chest. With a medical-gloved hand, the clinician places his or her thumb on the patient's lower molars on the involved side, as far back in the mouth as possible. The clinician's index and middle fingers grip the angle of the patient's mandible of the involved side, with the ring or little fingers held under the patient's mandible (depending on the size of the clinician's hand and patient's mandible). Using this grip, the clinician applies light distraction inferiorly to the patient's involved TMJ by pressing his or her thumb inferiorly against the lower molars (see Fig. 26-14).

Distraction, Anterior Glide, and Lateral Stretch

This technique is performed to increase the anterior and inferior movement of the mandible for the patient who can only achieve slight opening of the mouth. The patient and clinician positions are the same as those described for the distraction technique. Using the same grip as described earlier, the clinician applies light distraction inferiorly to the patient's involved TMJ by pressing his or her thumb inferiorly against the lower molars. In addition to the distraction, the clinician gradually superimposes an anterior glide of the head of the mandible at the TMJ and a lateral stretch to the joint on the opposite side. Following the technique, the patient is asked to open his or her mouth as much as possible, and the newly acquired range is assessed. The procedure is repeated gradually until the patient is able to open his or her mouth fully, or considerable improvement is attained.

Note: If the restriction of movement is bilateral, the technique may be performed on the opposite side.

Technique to Increase Full Mouth Closing[56,209]

This technique is used to increase the posterior movement of the mandible (retraction) for the patient, with an inability to fully close the mouth. The patient and clinician position is the same as described for the techniques to increase mouth opening. Using the same grip described for those techniques, the clinician gradually and maximally pushes posteriorly against the patient's involved mandible to produce a posterior glide of the head of the mandible at the TMJ (see Fig. 26-15).

Note: If the restriction of movement is bilateral, the same intervention may be performed on the patient's opposite side.

Extraoral Lateral Glide

This technique is used in the presence of severe pain, spasm, and marked limitation of movement caused by recent trauma.[96] The patient is positioned in supine, with the head being supported on a pillow. The patient is asked to rotate the head in the opposite direction of the involved TMJ. The clinician places the thumbs of both hands over the lateral pole of the condyle. Gentle oscillations are

performed over the lateral pole, or more distally depending on patient tolerance.

Extraoral Depression

T is technique also is used in the presence of severe pain, spasm, and marked limitation of movement caused by recent trauma.[96] T e patient is positioned in supine, with the head being supported on a pillow. T e clinician gently grasps the angle of the mandible with the index and the thumb bilaterally. Gentle oscillations are then performed in the direction of mandibular depression.

AUTOMOBIl IZATIOn S

Toothpick Exercise

T is exercise can be used for patients who demonstrate lateral deviation with mouth opening or closing. T e patient stands or sits facing a mirror. A thick line is drawn down the mirror using a wax crayon. T e patient wedges a toothpick between the lower incisors and lines up the toothpick with the line on the mirror. As the patient opens and closes the jaw, if the line becomes visible, the patient corrects the deviation before continuing the movement. If correction is not possible, the exercise is stopped to prevent incorrect learning by the controlling muscles.

Distraction Mobilization

T is technique can be taught to patients who demonstrate or report recurrent dislocations. To self-reduce a dislocation, the patient is instructed to place a gauze roll on the back inferior molars of both sides and to place his or her index fingers on the gauze. T e patient opens the mouth as wide as possible and then applies a downward force on the gauze and the molars, thereby creating a joint distraction. Following a successful reduction, ice or heat (whichever produces the optimal therapeutic effect) should be applied around the TMJ.

CHAPTER 27

The Thoracic Spine

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the thoracic intervertebral segment.
2. Outline the coupled movements of the thoracic spine, the normal and abnormal joint barriers, and the responses of the various structures to loading.
3. Perform a detailed objective examination of the thoracic musculoskeletal system, including palpation of the articular and soft-tissue structures, combined motion testing, position testing, passive articular mobility tests, and stability tests.
4. Evaluate the total examination data to establish the diagnosis and estimate the prognosis.
5. Describe the common pathologies and lesions of this region.
6. Apply a variety of manual techniques to the thoracic spine using the correct grade, direction, and duration.
7. Describe intervention strategies based on clinical findings and established goals.
8. Design an intervention plan based on patient education, manual therapy, and therapeutic exercise.
9. Evaluate intervention effectiveness in order to progress or modify an intervention.
10. Plan an effective home program, including spinal care and therapeutic exercise, and instruct the patient in this program.

OVERVIEW

T e thoracic spine serves as a transitional zone between the lumbosacral region and the cervical spine. Despite the fact that the thoracic spine has not enjoyed the same attention as other regions of the spine in terms of research, it can be a significant source of local and referred pain. T e thoracic spine is the most rigid region of the spine and, in this area, protection of the thoracic viscera takes precedence over segmental spinal mobility. In addition, the thorax is an important region of load transfer between the upper body (the head, cervical spine, and upper extremities) and the lower body (the lumbopelvic region and lower extremities).[1,2]

As each thoracic vertebra is involved in at least six articulations, and as many as thirteen, establishing the specific cause of thoracic dysfunction may not always be possible. T is task is made more difficult because of the inaccessibility of most of these joints.[3]

ANATOMY

T e thoracic spine (Fig. 27-1) forms a kyphotic curve between the lordotic curves of the cervical and lumbar spines. T e curve begins at T1–2 and extends down to T12, with the T6–7 disk space as the apex.[4] T e thoracic kyphosis is a structural curve that is present from birth.[5] Unlike the lumbar and cervical regions, which derive their curves from the corresponding differences in intervertebral disk (IVD) heights, the thoracic curve is maintained by the wedge-shaped vertebral bodies, which are about 2 mm higher posteriorly than anteriorly. T e thoracic spine can be divided into five regions based on anatomical and biomechanical differences.

- Cervicothoracic: T is region comprises the C7–T1 segment and the first rib.
- Vertebromanubrial: T is region, which has a slight overlap with the cervicothoracic region, includes the first two thoracic vertebrae, ribs 1 and 2, and the manubrium.
- Vertebrosternal: T is region includes T3–7, the third to seventh ribs, and the sternum.
- Vertebrochondral: T is region includes T8–10, together with the 8th, 9th, and 10th ribs.
- T oracolumbar. T is region includes T11 and T12, and the 11th and 12th ribs. At the thoracolumbar junction, typically located between T11 and L1, the changes in curvature from one of kyphosis to one of lordosis vary quite widely according to posture, age, and previous compression fractures (see Chapter 5) and resulting deformity.[6,7]

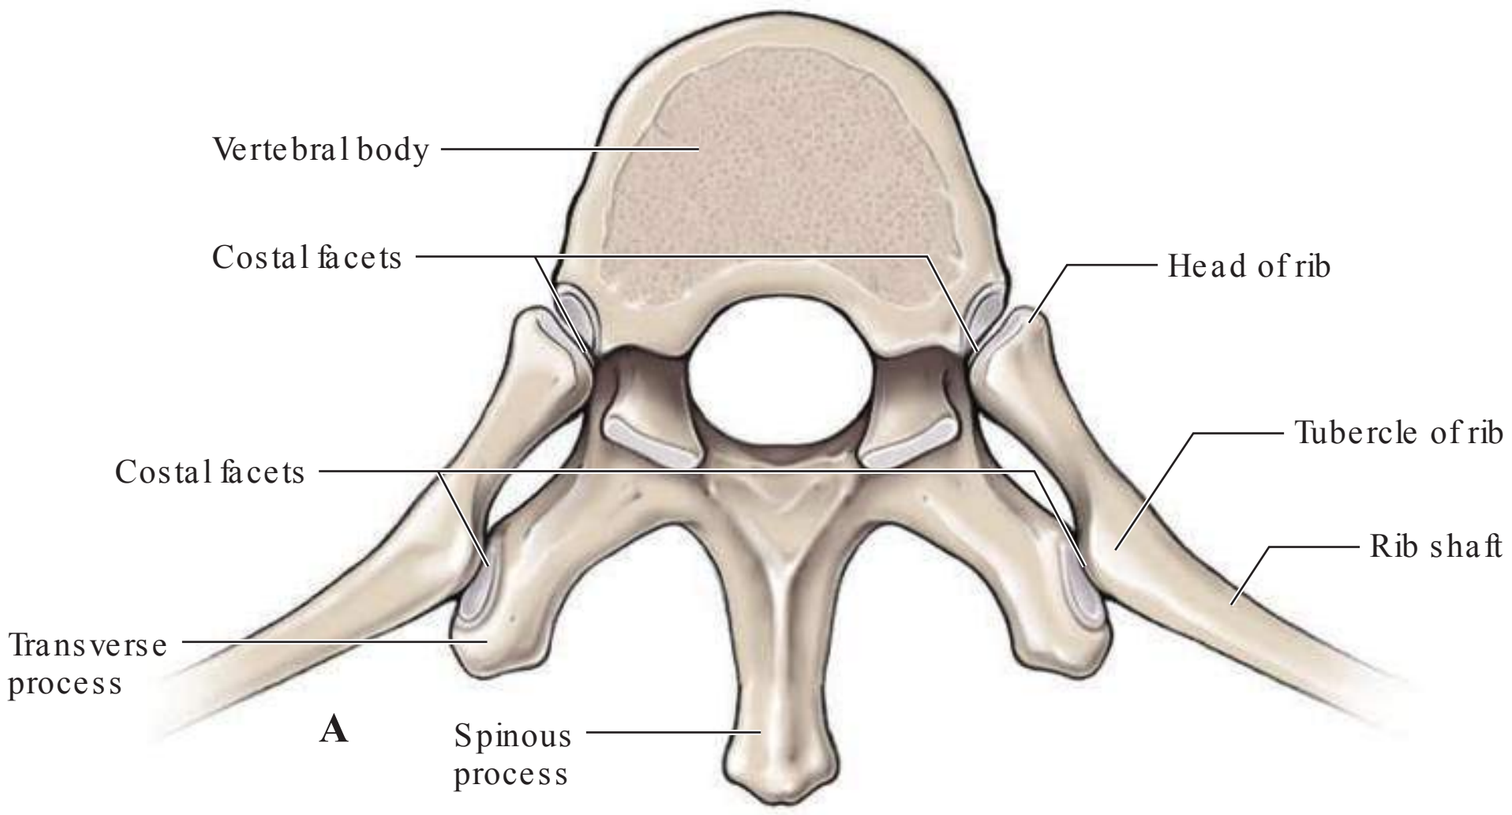

FIGURE 27-1 The thoracic spine and rib cage. (Reproduced, with permission, from Chapter 2. Anterior Thoracic Wall. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Thoracic Vertebra

T e thoracic vertebrae consist of the usual elements: the vertebral body (centrum), transverse processes, and spinous process (Fig. 27-1).

Vertebral Body

T e thoracic vertebral body (Fig. 27-1) is roughly as wide as it is long so that its anteroposterior and mediolateral dimensions are of equal length.[8] T e anterior surface of the body is convex from side to side, whereas the posterior surface is deeply concave.[8] T e first thoracic vertebra is atypical and has a large, nonbifid spinous process, the superior aspect of which tends to lie in the same transverse plane as the zygapophyseal joints of T1 and T2. On the anterior aspect of the transverse process, there is a deep and concave facet which articulates with the convex facet of the first rib to form the costotransverse joint. T e height, end-plate cross-sectional area, and bone mass of the vertebral bodies increase cranially to caudally, particularly in the lower levels.[9,10] Progressive wedging of the thoracic vertebral bodies occurs with increasing age in the majority of individuals, with disk space narrowing at multiple levels occurring from the third decade of life.[11] T e vertebral bodies of most of the thoracic spine differ from those of the cervical and lumbar vertebrae because of the presence of a demifacet on each of their lateral aspects for articulation with the ribs (the costovertebral joint; see later discussion).

Intervertebral Disk

T e IVDs of the thoracic spine have been poorly researched, although preliminary studies seem to indicate that the typical thoracic disk appears to have been adapted from a cervical design rather than from a lumbar design.[12] T e vertebral bodies of thoracic vertebrae 2–10 increase in size and change shape down the vertebral column and, importantly, each has two demifacets for the attachment of ribs.[12] T e IVDs of this region are narrower and flatter than those in the cervical and lumbar spine and contribute approximately one-sixth of the length of the thoracic column.[13] Disk size in the thoracic region gradually increases from superior to inferior. T e disk height to body height ratio is 1:5, compared to 2:5 in the cervical spine, and 1:3 in the lumbar spine,[14,15] making it the smallest ratio in the spine and affording the least amount of motion.[16] Motion is further restricted by the orientation of the lamella of the annulus fibrosus (AF),[17] and the relatively small nucleus pulposus (NP), which is more centrally located within the AF, and has a lower capacity to swell.[18] T e roughly circular cross-section of the thoracic disk allows the force of torsion to be evenly distributed around its circumference, making it better able to withstand these kinds of forces.[19]

In the thoracic spine, the segmental nerve roots are mainly situated behind the inferior-posterior aspect of the upper vertebral body rather than behind the disk, which reduces the possibility of root compression in impairments of the thoracic disk.[20] In a review of 280 patients, Arce and Dohrmann[21] found that thoracic disk herniation constitutes 0.25–0.75% of all disk herniations. Because the intervertebral foramina are quite large at these levels, osseous contact with the nerve roots is seldom encountered in the thoracic spine,[20] and, as the dermatomes in this region have a fair amount of overlap, they cannot be relied upon to determine the specific nerve root involved.

In contrast to the cervical and lumbar regions, where the spinal canal is triangular/oval in cross-section and offers a large lateral excursion to the nerve roots, the midthoracic spinal canal is small and circular (Fig. 27-1), becoming triangular at the upper and lower levels. At the levels of T4–9, the canal is at its narrowest.[20] T e spinal canal is also restricted in its size by the pedicles, remaining within the confines of the vertebra and not diverging as they do in the cervical spine. T is would tend to predispose the spinal cord to compression more than in the cervical spine, were it not for the smaller cord size and more oval shape of the thoracic canal. Despite this, central disk protrusions are more common in the thoracic region than in other regions of the spine, and, because the NP is small in the thorax, protrusions are invariably of the annular type, and nuclear protrusions are rare.[20] Complicating matters is the fact that this is an area of poor vascular supply, receiving its blood from only one radicular artery. T is renders the thoracic spinal cord extremely vulnerable to damage by extra dural masses or by an overzealous manipulation.

Transverse Processes

T e transverse processes of the thoracic spine are oriented posteriorly (i.e., they point backward) and are located directly between the inferior articulating process and the superior articulating process of the zygapophyseal joints of each level (Fig. 27-1). T is anatomical feature makes the transverse processes useful as palpation points, when performing mobility testing in the midthorax.

T e transverse processes of the first 10 thoracic vertebrae differ from those of the cervical and lumbar spines because of the presence of a costal facet on the transverse process, which articulates with the corresponding rib to form the costotransverse joint (see later discussion). At the T11 and T12 levels, the costotransverse joint is absent because ribs 11 and 12 do not articulate with the transverse processes but rather with the vertebral body.

Spinous Processes

Two short and thick laminae come together to form the spinous process (Fig. 27-1). T e spinous processes of the thoracic region are long, slender, and triangular shaped in cross-section. Although all of the thoracic spinous processes point obliquely downward, the degree of obliquity varies. T e first three spinous processes and the last three are almost horizontal, whereas those of the midthorax are long and steeply inclined. T7 has the greatest spinous process angulation.

As elsewhere in the spine, the thoracic vertebrae are designed to endure and distribute the compressive forces produced by weight bearing, most of which is borne by the vertebral bodies. T e compressive load at T1 is approximately 9% of body weight, increasing to 33% at T8 and 47% at T12.[22,23]

T e thoracic vertebrae are classified as typical or atypical, with reference to their morphology. T e typical thoracic vertebrae are found at T2–9, although T9 may be atypical in that its inferior costal facet is frequently absent. T e atypical thoracic vertebrae are T1, T10, T11, and T12.

T e first vertebra (T1) resembles C7. T e centrum of T1 demonstrates a larger transverse than the anteroposterior dimension of the vertebral body, being almost twice as wide as its length, and the spinous process is usually at least as long as that of C7. T ere are two ovoid facets on either side of the T1 vertebral body for articulation with the head of the first rib. T e inferior aspect of the vertebral body of T1 is flat and contains a small facet at each posterolateral corner for articulation with the head of the second rib.

Approximately 32 structures attach to the first rib and body of T1.[22,23] Because of the ring-like structure of the ribs, and their attachments both anteriorly and posteriorly, the thoracic spine and ribs can be viewed as a cage-like structure forming a series of concentric rings. Any movement occurring at the various joints of each ring (costovertebral, costotransverse, sternocostal, and zygapophyseal joints) has the potential to influence motions at the other joints within the ring, or at the neighboring segments.

T e third vertebra is the smallest of the thoracic vertebra. T e T9 vertebra may have no demifacets below, or it may have two demifacets on either side (in which case, the T10 vertebra will have demifacets only at the superior aspect). T e T10 vertebra has one full rib facet located partly on the body of the vertebra and partly on the tubercle. It does not articulate with the 11th rib and so does not possess any inferior demifacets, and occasionally there is no facet for the rib at the costotransverse joint.

T e T11 and T12 segments form the thoracolumbar junction. T e T11 vertebra has complete costal facets, but no facets on the transverse processes for the rib tubercle. T e T12 vertebra only articulates with its own ribs and does not possess inferior demifacets.

Ligaments

T e common spinal ligaments are present at the thoracic vertebrae, and they perform much the same function as they do elsewhere in the spine. However, the anterior longitudinal ligament in this region is narrower but thicker compared with elsewhere in the spine,[8] whereas the posterior longitudinal ligament is wider here at the level of the IVD, but narrower at the vertebral body than in the lumbar region.[24]

Zygapophyseal Joints

T e zygapophyseal joints of the upper thoracic spine show some morphological features of the cervical region, and similarly the joints of the lower thoracic spine progressively approximate those of the upper lumbar region.[25] T e middle segments of the thoracic spine are designed for less mobility, as the thoracic cage articulations limit sagittal plane motion while accommodating axial displacements.[25,26]

CLINICAL PEARL

The articulating facets of the thoracic zygapophyseal joints are quite different from those of the cervical and lumbar spines because they are oriented in a more coronal direction, with the angle of inclination changing, depending on the segmental level.

- The upper segments are inclined at 45–60 degrees to the horizontal in a similar fashion as to those of the cervical spine.
- The middle segments are inclined at 90 degrees to the horizontal in the typical thoracic form.
- The lower segments are inclined as in the lumbar spine. Zygapophyseal tropism (the moving toward or away from a stimulus) occurs most frequently at T11–12.[27] The inferior articular facets of T12 are invariably lumbar in orientation and concavity, with the orientation changing by 90 degrees at either T11 or T12, allowing pure axial rotation to occur.[28]

T e superior and inferior facets of the zygapophyseal joints arise from the upper and lower parts of the pedicle of the thoracic vertebra. T e superior facet lies superiorly with the articular surface on the posterior aspect, whereas the inferior facet lies inferiorly with the articular surface on the anterior (ventral) aspect. T e degree of superoinferior and mediolateral orientation is slight. T e superior facet arises from near the lamina–pedicle junction and faces posteriorly, superiorly, and laterally.

T e inferior articulating facet arises from the laminae to face anteriorly, inferiorly, and medially, lying posterior to the superior facet of the vertebra below. T e facet surfaces are concave anteriorly and convex posteriorly, bringing the axis of rotation through the centrum rather than through the spinous process, as in the lumbar vertebrae. T is results in the biomechanical center of rotation coinciding with the actual center of rotation formed by body weight.[29]

T e zygapophyseal joints function to restrain the amount of flexion and anterior translation of the vertebral segment and to facilitate rotation.[22] T ey appear to have little influence on the range of side bending.[22]

Ribs

T e bony thoracic cage is formed by 12 pairs of ribs, the sternum, the clavicle, and the vertebrae of the thoracic spine (Fig. 27-1). T e first rib is the shortest of the 12, and the broadest at its anterior end. T e primary function of the rib cage is to protect the heart and lungs. All of the ribs of the cage are different from each other in size, width, and curvature, although they share some common characteristics. T e rib length increases further inferiorly until the seventh rib, af er which they become progressively shorter. Ribs 1–7 are named true ribs because their cartilage attaches directly to the sternum. T e remaining ribs are false ribs, so named because their distal attachment is to the costochondral cartilage of their superior neighbor.

Typical Ribs

Ribs 3–9 are typical ribs. T e typical rib is characterized by a posterior end, which is composed of a head, neck, and tubercle. T e head of the typical rib is characterized as two articular facets, a superior costal facet, and an inferior costal facet.

a. T e superior facet attaches to the costal semilunar demifacet of the vertebra above its level.

b. The inferior facet attaches to the costal semicircular demifacet of the vertebra of the same level.

The head of the typical rib projects upward in a very similar manner to that of the uncinate process in the cervical spine and, in fact, develops in much the same way during childhood, appearing to play a similar mechanical role.[8] The head consists of a slightly enlarged posterior end, which is divided by a horizontal ridge. The ridge serves as an attachment for the intraarticular ligament. The intraarticular ligament, which travels between the head of the rib and the IVD, bisects the joint into superior and inferior portions. Each of these portions normally contains a demifacet for articulation with the synovial costovertebral joints.

The tubercle of the typical rib lies on the outer surface, where the neck joins the shaft and is more prominent in the upper parts than in the lower. The articular portion of the tubercle presents an oval facet for articulation at the costotransverse joint (Fig. 27-1).

The convex shaft of the rib is connected to the neck at the rib angle. The upper border of the shaft is round and blunt, whereas the inferior aspect is thin and sharp.[8] The anterior end of the shaft has a small depression at the tip for articulation at the costochondral joint.

Atypical Ribs

The first, second, tenth, eleventh, and twelfth ribs are considered atypical since they only articulate with their own vertebra via one full facet, and the lower two do not articulate with the costochondrium anteriorly.[8] The atypical first rib is small but massively built. Being the most curved and the most inferiorly orientated rib, it slopes sharply downward from its vertebral articulation to the manubrium. The head is small and rounded and articulates only with the T1 vertebra. The first costal cartilage is the shortest and this, together with the fibrous sternochondral joint (Fig. 27-1), contributes to the overall stability of the first ring of the rib cage. The first rib attaches to the manubrium just under the sternoclavicular joint, and the second rib articulates with the sternum at the manubriosternal junction. The atypical second rib is longer and is not as flat as the first rib. It attaches to the junction of the manubrium and the body of the sternum.

The atypical 10th rib has only a single facet on its head, because of its lack of articulation with the vertebra above. The 11th and 12th ribs do not present tubercles and have only a single articular facet on their heads. The 11th and 12th ribs remain unattached anteriorly but end with a small piece of cartilage.

Attachment and Orientation of the Ribs

The attachment of the ribs to the sternum is variable (Fig. 27-1). The upper five, six, or seven ribs have their own cartilaginous connection (see "Sternocostal Joint" section).[8] The cartilage of the eighth rib ends by blending with the seventh. The same situation pertains for the ninth and the tenth ribs, thus giving rise to a common band of cartilage and connective tissue.

The strong ligamentous attendance, and the presence of the two joints (costovertebral and costotransverse) at each level, severely limits the amount of movement permitted here to slight gliding and spinning motions, with morphology determining the function of each rib.

The orientation of the ribs increases from being horizontal at the upper levels to being more downwardly oblique in the inferior levels of the thoracic spine (a point worth remembering when performing palpation).

CLINICAL PEARL

The cervical rib is a rare anatomic variant estimated to occur in approximately 0.5–1% of the population and bilaterally in 66–80% of these cases.[18] Diagnosis is most often incidental, as a result of routine chest radiographs or in patients developing thoracic outlet syndrome (see Chapter 25).[30]

Costovertebral Joint

The thoracic vertebrae are connected to their adjacent vertebrae by the bilateral hyalinated, and synovial, costovertebral joints, and their surrounding ligaments (see Fig. 27-1). The costovertebral articulation also forms an intimate relationship between the head of the rib and the lateral side of the vertebral body (see Fig. 27-1). The 1st, 11th, and 12th ribs articulate fully with their own vertebrae via a single costal facet, without any contact with the IVD, while the remaining ribs articulate with both their own vertebra and the vertebra above, as well as to the IVD. This could potentially predispose the 1st, 11th, and 12th costovertebral joints to early arthritic changes, as a result of more mechanical stress compared to the 2nd to the 10th ribs.[31]

The radiate ligament connects the anterior aspect of the rib head to the bodies of two adjacent vertebrae and their intervening disk in a fanlike arrangement. Each of the three bands of the radiate ligament has different attachments.

1. The superior part runs from the head of the rib to the body of the superior vertebra.
2. The inferior part runs to the body of the inferior vertebra.
3. The intermediate part runs to the intervening disk.

Oda et al.[32] reported that the costovertebral joint and rib cage confer stability on the thoracic spine. They performed symmetrically applied resections of the posterior elements first, followed by resection of the bilateral costovertebral joints and then complete obliteration of the rib cage. Their conclusion was that the thoracic spine may become unstable when the posterior elements and the bilateral costovertebral joints are obliterated. In addition, there is an increase in the neutral zone and range of motion in both side bending and rotation, indicating that these joints provide a stabilizing influence during coupled motions.[32]

Feiertag et al.[33] reported that rib head joint resection showed significant increases in thoracic spinal motion in the sagittal and coronal planes. As the ossification of the head of the rib is not developed at the superior costovertebral joint until about age 13, younger individuals, such as gymnasts, can demonstrate a vast amount of thoracic rotation and side bending.

Costotransverse Joint

T is is a synovial joint located between an articular facet on the posterior aspect of the rib tubercle and an articular facet on the anterior aspect of the transverse process, which is supported by a thin fibrous capsule (see Fig. 27-1). In the lower two thoracic vertebral segments, this articulation does not exist.

T e neck of the rib lies along the entire length of the posterior aspect of the transverse process. T e short and deep costotransverse ligament runs posteriorly from the posterior aspect of the rib neck to the anterior aspect of its transverse process, filling the costotransverse foramen that is formed between the rib neck and its adjacent transverse process. T e ligament has two divisions.

1. T e superior costotransverse ligament, also known as the interosseous ligament, or ligament of the neck of the rib, is formed in two layers. T e anterior layer, which is continuous with the internal intercostal membrane laterally, runs from the neck of the rib up and laterally to the inferior aspect of the transverse process above. T e posterior layer runs up and medially from the posterior aspect of the rib neck to the transverse process above.
2. T e lateral costotransverse ligament runs from the tip of the transverse process laterally to the tubercle of its own rib. It is short, thick, and strong but is of en damaged by direct blows to the chest (e.g., punch, kick).

Very little posteroanterior or anteromedial–posterolateral translation is available at this joint. Jiang et al.[34] reported that the superior costotransverse ligaments are very important in maintaining the lateral stability of the spine.

CLINICAL PEARL

Working together, the costotransverse and the costovertebral joints help provide stability to the thoracic spine.

Sternum

T e sternum consists of three parts: the manubrium, the body, and the xiphoid process.

T e manubrium (Fig. 27-1) is broad and thick superiorly and narrower and thinner inferiorly, where it articulates with the body of the sternum. T e articulation between the manubrium and the sternum is usually a symphysis, with the ends of the bones being lined with hyaline cartilage. T is manubriosternal symphysis remains separate throughout life although ossification can occur. On either side of the suprasternal notch are articulating facets for the clavicles, and below these are the facets for the first rib. On the immediate inferolateral aspects of the manubrium are two more small facets for the cartilage of the second rib.

T e body of the sternum is made up of the fused elements of four sternal bodies, and the vestiges of these are marked by three horizontal ridges. T e upper end of the body articulates with the manubrium at the sternal angle. A facet at the superior end of the body laterally provides a joint surface common with the manubrium for the second costal cartilage. On each lateral border of the sternum are four other notches that articulate with the costal cartilages of the third through sixth ribs. T e third rib has the deepest fossa on the sternum, indicating that it may serve as the axis for rotation and side bending during arm elevation. T7 articulates with both the sternum and the xiphoid.

T e xiphisternum, or xiphoid process (see Fig. 27-1), is the smallest part of the sternum. It begins life in a cartilaginous state, but, in adulthood, the upper part ossifies.

A study[35] examining the effect of removal of the entire sternum from the intact thorax found that its removal produced an almost complete loss of the stiffening effect of the thorax.

Sternocostal Joint

T e first, sixth, and seventh costal cartilages are each linked to the sternum by a synchondrosis. T e second to fif h ribs are each connected to the sternum through a synovial joint, whereby the cartilage of the corresponding rib articulates with a socket-like cavity in the sternum.[36]

In all of these joints, the periosteum of the sternum and the perichondrium of the costal cartilage are continuous. A thin fibrous capsule, present in the upper seven joints, attaches to the circumference of the articular surfaces, blending with the sternocostal ligaments. T e surfaces of the joints are covered with fibrocartilage and are supported by capsular, radiate sternocostal, or xiphocostal and intraarticular ligaments. T e joint is capable of about 2 degrees of motion from full inspiration to full expiration and allows the full excursion of the sternum in these activities.

Muscles

A large number of muscles arise from and insert on the thoracic spine and ribs (Fig. 27-2). T e muscles of this region can be divided into those that are involved in spinal or extremity motion, and those that are involved in respiration (Tables 27-1 and 27-2).

Spinal and Extremity Muscles

Spinal Muscles

Iliocostalis T oracis. T e iliocostalis thoracis consists of several muscle straps that link the thoracic vertebrae and sacrum with the lower six or seven ribs. T e muscle straps have a number of tendons, varying in different individuals, which insert in all angles in the lower six ribs. T e function of the muscle is to extend the spine when working bilaterally and to sidebend the spine ipsilaterally when working alone. T e iliocostalis consists of three subdivisions—iliocostalis lumborum, iliocostalis thoracis, and iliocostalis cervicis—which are a part of the external portion of the long erector spinae muscle group. T e muscle receives its nerve supply by the posterior (dorsal) rami of the thoracic nerves.

Longissimus T oracis. T e longissimus thoracis muscles originate with the intercostalis muscles from the transverse processes of the lower thoracic vertebrae. T ey insert into all of the ribs and into the ends of the transverse processes of the upper lumbar vertebrae. T e function of the muscle is to extend the spine when working bilaterally and to side bend the

spine ipsilaterally when working alone. The muscle is innervated by the posterior (dorsal) rami of the thoracic nerves.

Spinalis Thoracis. The spinalis thoracis muscle (spinalis dorsi) originates from the spinous processes of the upper lumbar and two lower thoracic vertebrae. It inserts in the spinous processes of the middle and upper thoracic vertebrae. The function of the muscle is to extend the spine. The muscle is innervated by the posterior (dorsal) rami of the thoracic nerves.

Semispinalis Thoracis. The semispinalis thoracis consists of long straps of muscle that stretch along and surround the vertebrae of the spine. The muscle can have between four and eight upper ends, which originate from the transverse processes of the T6–10. These straps of muscle insert in the spinous processes of the first four thoracic and fifth and seventh processes of C6–T4. The function of the muscle is to extend the spine when working bilaterally and to rotate the spine contralaterally when working alone. The semispinalis thoracis is innervated by the posterior (dorsal) rami of the thoracic nerves.

Multifidus. The multifidus is a deep back muscle that runs along the entire spine and lies deep to the erector spinae muscles. It originates from the sacrum, sacroiliac ligament, mammillary processes of the lumbar vertebrae, transverse processes of the thoracic vertebrae, and the articular processes of the last four cervical vertebrae. The multifidus consists of numerous bundles of fibers that cross over two to five vertebrae at a time and insert into the entire length of the spinous process above. The function of the muscle is to extend the spine when working bilaterally and to rotate the spine minimally contralaterally when working alone. The thoracic multifidus is innervated by the posterior (dorsal) rami of the thoracic spinal nerves.

Rotatores Thoracis (Longus and Brevis). The rotatores muscles are deep spinal muscles that lie beneath the multifidus muscles. The rotatores brevis muscle lies just deep to the rotatores longus muscle. The rotatores muscles are the best developed in the thoracic region. There are a total of 11 small, quadrilateral rotatores muscles on each side of the spine. Each muscle arises from the transverse process of the vertebra and extends inward to the vertebra above. The rotatores muscles help rotate the appropriate thoracic segment. They are innervated by posterior (dorsal) rami of the thoracic spinal nerves.

Intertransversarii. The intratransversals are small muscles located between the transverse process of the vertebrae. In the thoracic region, they are single-bellied muscles and exist only from T10–11 to T12–L1. The function of the muscle is to sidebend the spine ipsilaterally. The muscle is innervated by the posterior (dorsal) rami of the thoracic spinal nerves.

The other spinal muscles of the thoracic region act primarily on the cervical spine. These include the trapezius, levator scapulae, and anterior, posterior, and middle scalenes (see Chapter 25).

Extremity Muscles. The muscles of the thoracic region that act primarily on the extremities include the pectoralis major, latissimus dorsi, and serratus anterior (see Chapter 16).

Respiratory Muscles

The respiratory system is essentially a robust, multimuscle pump (Fig. 27-3). Connections to the respiratory mechanism have been found to exert a strong influence on such areas as the shoulder and pelvic girdles, as well as the head and neck. The primary task of the respiratory muscles is to displace the chest wall and, therefore, move gas in and out of the lungs to maintain arterial blood gas and pH homeostasis. The importance of normal respiratory muscle function can be appreciated by considering that respiratory muscle failure caused by fatigue, injury, or disease could result in an inability to maintain blood gas and pH levels within an acceptable range, which could have lethal consequences. Restoration of the respiratory mechanism is, thus, an essential element of thoracic intervention.

The actions of various respiratory muscles, which are broadly classified as inspiratory or expiratory, based on their mechanical actions, are highly redundant and provide several means by which air can be effectively displaced under a host of physiologic and pathophysiologic conditions.[37,38]

At rest, movement of air into and out of the lungs is the result of the recruitment of several muscles,[39–41] and the expiratory phase of breathing at rest is also associated with active muscle participation.[41] In a resting man, the tidal volume is the result of the coordinated recruitment of the diaphragm, the parasternal intercostal, and the scalene muscles (Tables 27-1 and 27-2).[43,44]

Although some have argued that the performance of the respiratory muscles does not limit exercise tolerance in normal healthy adults,[45,46] heavy or prolonged exercise has been shown to impair respiratory muscle performance in

humans.[47,48] Thus, an interest in the adaptability of respiratory muscles to endurance-type exercise has grown significantly during the last decade.

The primary muscles of respiration include the diaphragm, the sternocostal, and the intercostals. The secondary muscles of respiration are the anterior/medial scalenes, serratus posterior, pectoralis major and minor, and, with the head fixed, the sternocleidomastoid.[8]

Diaphragm

Anatomically, the diaphragm muscle may be divided into sternal, costal, and lumbar parts.

- The sternal fibers originate from two slips at the back of the xiphoid process.
- The costal fibers originate from the lower six ribs and their costal cartilages.
- The lumbar fibers originate from the crura of the lumbar vertebra, and the medial and lateral arcuate ligaments.

CLINICAL PEARL

Patients with bilateral diaphragm paralysis or severe weakness present a striking clinical picture, with orthopnea as the major symptom. Lesser degrees of diaphragm weakness, however, are hard to detect and need specific testing.

Functionally and metabolically, the diaphragm can be classified as two muscles.[49,50]

1. The crural (posterior) portion that inserts into the lumbar vertebrae.
2. The costal portion that inserts into the xiphoid process of the sternum and into the margins of the lower ribs.

Thus, the muscle is attached around the thoracoabdominal junction circumferentially. From these attachments, the fibers arch toward each other centrally to form a large tendon. Contraction of the diaphragm pulls the large, central tendon inferiorly, producing diaphragmatic inspiration (see later discussion). The diaphragm has a phrenic C3–4 motor innervation and sensory supply by the lower six intercostal nerves.

Intercostals

Between the ribs are the intercostal spaces, which are deeper both in front and between the upper ribs. Between the ribs lie the internal and external intercostal muscles, with the neurovascular bundle lying beneath each rib.

The intercostal muscles, together with the sternalis (or sternocostalis or transversalis thoracis), phylogenically form from the hypomeric muscles. These muscles correspond to their abdominal counterparts, with the sternalis being homologous to the rectus abdominis, and the intercostals homologous to the external oblique.[8]

External Intercostals. The external intercostal muscles (Fig. 27-2), of which there are 11, are laid in a direction that is superoposterior to inferoanterior (run inferiorly and medially in the front of the thorax and inferiorly and laterally in the back). Because of the oblique course of the fibers, and the fact that leverage is greatest on the lower of the two ribs, the muscle pulls the lower rib toward the upper rib, which results in inspiration. The external intercostals attach to the lower border of one rib and the upper border of the rib below, extending from the tubercle to the costal cartilage. Posteriorly, the muscle is continuous with the posterior fibers of the superior costotransverse ligament. The action of the external intercostals is believed to be entirely inspiratory,[43] although the muscles also counteract the force of the diaphragm, preventing the collapse of the ribs.[40] Innervation of this muscle is supplied by the adjacent intercostal nerve.

Internal Intercostals. The internal intercostals (see Fig. 27-2), which also number 11, have their fibers in an inferoposterior to a superoanterior direction. The internal intercostals are found deep to the external intercostals and run obliquely, and perpendicular, to the externals. The posterior fibers pull the upper rib down, but only during enforced expiration.[40,43] The internal intercostals extend from the posterior rib angles to the sternum, where they end posteriorly. They are continuous with the internal membrane, which then becomes continuous with the anterior part of the superior costotransverse ligament. Innervation of this muscle group is supplied by the adjacent intercostal nerve.

Transverse Intercostals (Intima). The deepest of the intercostals, the transverse intercostals are attached to the internal aspects of two contiguous ribs. They become progressively more significant and developed, further down the thorax. This is muscle is used during forced expiration.[40,43]

Transversus Thoracis. The transversus thoracis is a triangular-shaped sheet muscle, which originates from the posterior (dorsal) surface of the sternum and covers the inner surfaces of both the sternum and the second to eighth sternal costal cartilages. The apex of the muscle points cranially, with muscle slips running inferolaterally and eventually inserting on the sternal ribs quite close to the costochondral junctions. Morphologically, the transversus thoracis is similar to the anterior (ventral) part of the transversus abdominis. Its function is to draw the costal cartilages down. The muscle is innervated by the adjacent intercostal nerves.

Levator Costae

These consist of 12 strong short muscles that turn obliquely (inferolaterally), parallel with the external intercostals, from the tip of the transverse process to the angle of the rib, extending from C7 to T11 transverse processes. These muscles, which are innervated by the lateral branch of the posterior (dorsal) ramus of the thoracic nerve, function to raise the rib, but their importance in respiration is argued. The levator costae may also be segmentally involved in rotation and side bending of the thoracic vertebra.

Serratus Posterior Superior

The serratus posterior superior runs from the lower part of the ligamentum nuchae, the spinous processes of C7 and T1–3, and their supraspinous ligaments, to the inferior border of the second through fifth ribs, lateral to the rib angle.

The muscle receives its nerve supply from the second through fifth intercostal nerves. Its function is unclear, but it is thought to elevate the ribs.[8]

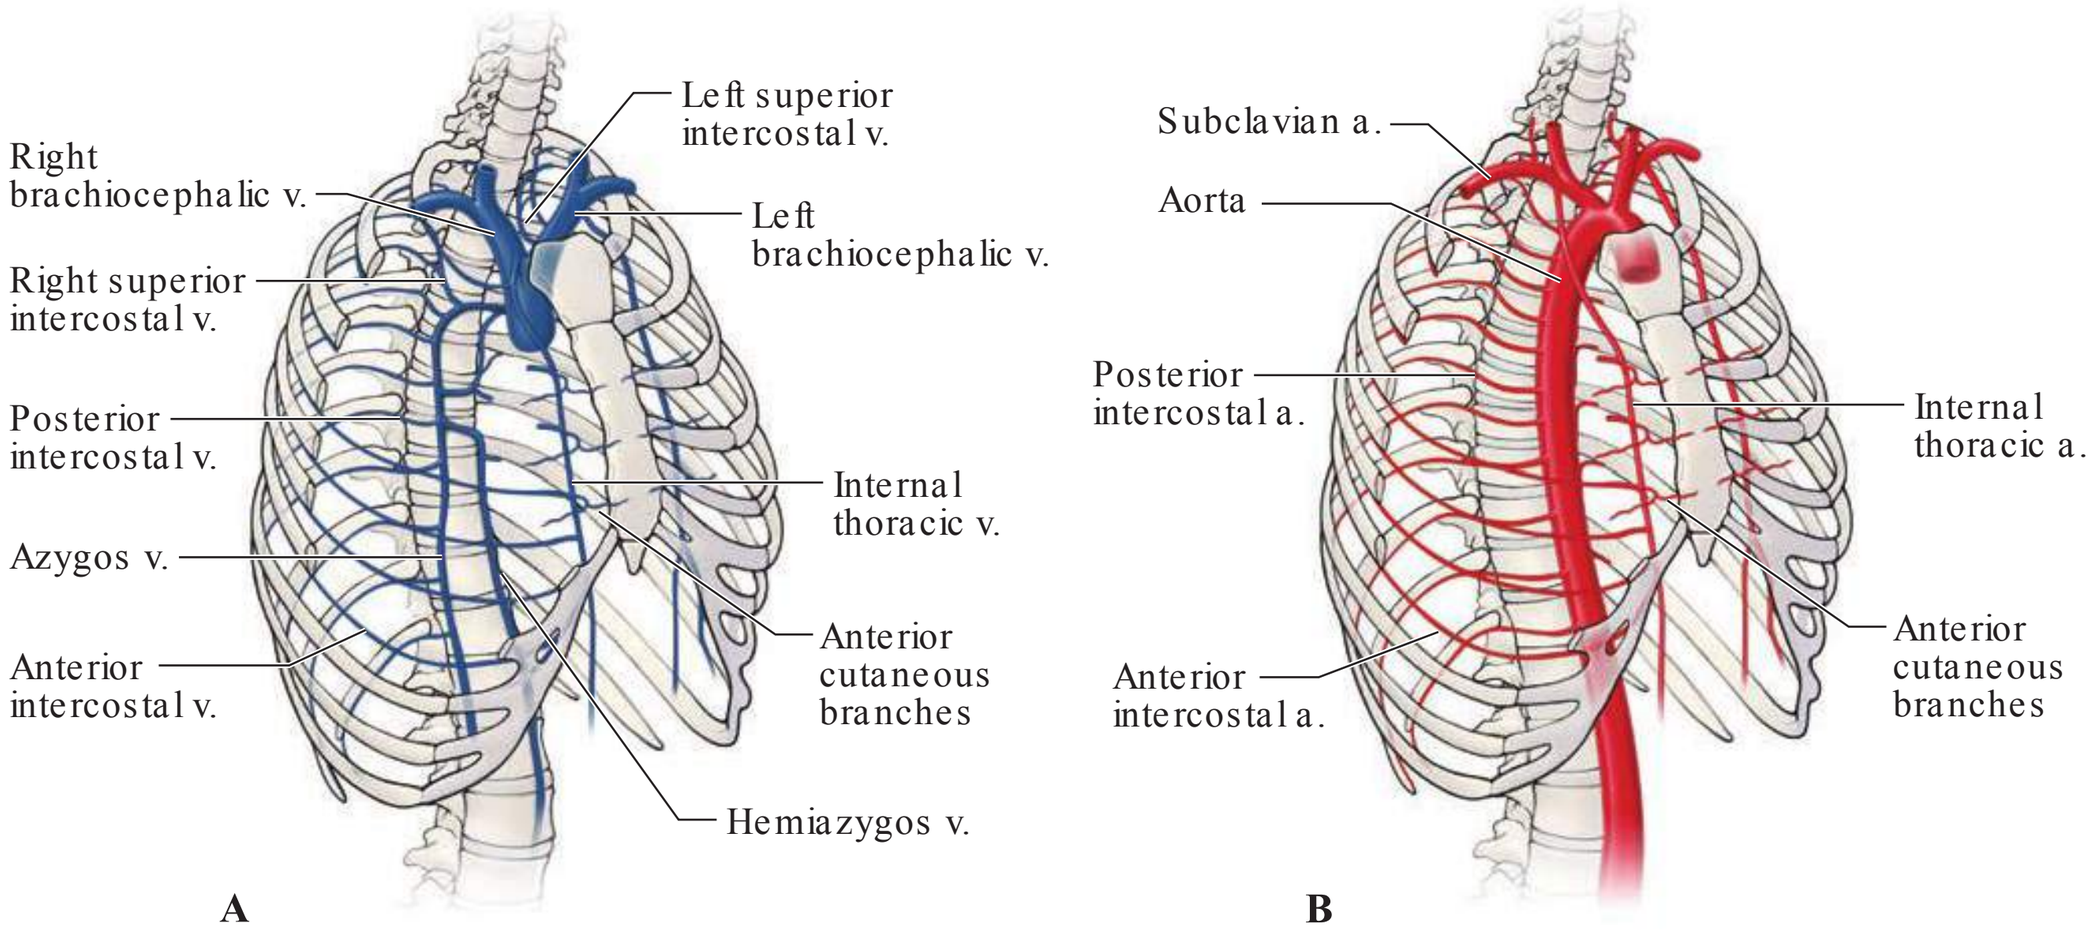

FIGURE 27-4 Vasculature of the thoracic region. (Reproduced, with permission, from Chapter 2. Anterior Thoracic Wall. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Serratus Posterior Inferior

The muscle arises from the spines and supraspinous ligaments of the two lower thoracic and the two or three upper lumbar vertebrae. It attaches to the inferior border of the lower four ribs, lateral to the rib angle.

The muscle receives its nerve supply from the anterior (ventral) rami of the 9th through 12th thoracic nerves. Its function is unclear, but it is thought to pull the ribs downward and backward.

Vascular Supply

The blood supply to this region is provided mainly by the posterior (dorsal) branches of the posterior intercostal arteries (Fig. 27-4) while the venous drainage occurs through the anterior and posterior venous plexuses. The spinal cord region between T4 and T9 is poorly vascularized.[51]

Neurology

The spinal canal in this region is narrow, with only a small epidural space between the cord and its osseous environment.[51] Innervation of the thoracic spinal canal is by the sinuvertebral nerve, which arises from the nerve root and reenters the epidural space.

The thoracic spinal cord is unusually susceptible to injury because it occupies a greater percentage of the total cross-sectional area of its surrounding spinal canal than do the cervical or lumbar sections of the spinal cord, and the thoracic cord is tightly packed in the canal and easily injured by displaced fragments of bone or disk material.[52] Furthermore, the blood supply of the midthoracic spinal cord is tenuous, and seemingly trivial injuries can disrupt the blood supply to a substantial portion of the thoracic cord and result in devastating neurologic deficits.[53]

In the thoracic region, there is great variability in the topography of the nerves and the structures that they serve.[54] Typically, the spinal root arises from the lateral end of the spinal nerve but, in 25% of cases, the spinal root is made up of two parts that arise from the superior border of the spinal nerve.[55] The thoracic spinal nerves are segmented into posterior (dorsal) primary and anterior (ventral) primary divisions (see Chapter 3). As elsewhere, the dermatomes of this region are considered to represent the cutaneous region innervated by one spinal nerve through both of its rami.[56]

The peripheral nerves, which travel through the thoracic spine and chest wall, include the posterior (dorsal) scapular, thoracodorsal, and long thoracic nerves (see Chapter 3).

BIOMECHANICS

Knowledge of the regional biomechanics of the thoracic spine and rib cage assists the clinician in the interpretation of active movement and motion palpation examination in relation to the patient's symptoms.[57] The thoracic spinal segments possess the potential for a distinctive array of movements. Most of the understanding with regard to the biomechanics of the thoracic spine is based largely on the ex vivo studies of White,[21] and Panjabi et al.,[1,58] and a variety of 'clinical models.[28,59] In addition, although normative ranges of spinal motion have been reported for the lumbar spine, no such reliable data exists for the thoracic region.[60]

It is widely recognized that the mechanical behavior of the spine is influenced by load.[61] Axial load has been shown to increase motion segment stiffness and decrease mobility. In addition, due to the modifying influence of the cage-like structure of the ribs, which provide a significant degree of stability,[34] and the kyphotic shape of the curve, the biomechanics of the thoracic spine is considerably different from those of the lumbar and cervical regions. The increased stability/reduced mobility of the thoracic segments has been reported to produce three primary effects.[23,62]

1. It influences the motions available in other spinal regions as well as the shoulder girdle.
2. It increases the potential for postural impairments.[63]
3. It provides an important weight-bearing mechanism for the vertebral column.[64] The load-bearing capacity of the spine has been found to be up to three times greater with an intact rib cage.[35,65]

Other biomechanical studies have investigated the stabilizing effects of the individual components of the thoracic spine.[32,66]

- The IVD can be regarded as the most important stabilizer in the thoracic functional unit mechanics.
- The rib head joints serve as stabilizing structures to the human thoracic spine under flexion–extension, side bending, and axial rotation loading, and resection after diskectomy increases range of motion by approximately 80% under all loading modes.
- The lateral portion of the facet joints plays an important role in providing spinal stability.
- In the thoracic spine, total resection of the posterior ligamentous complex leads to an approximately 40% increase in the range of motion under flexion–extension, side bending, and axial rotation loading.

Flexion

Flexion of the thoracic spine in weight bearing is initiated by the abdominal muscles and, in the absence of resistance, is continued by gravity, with the spinal erector muscles eccentrically controlling the descent. Flexion may also occur during bilateral scapular protraction.

There are about 4–5 degrees of flexion available at the upper thoracic levels, 6–8 degrees in the middle layers, and 9–15 degrees in the lower levels,[22] giving an overall total range for thoracic flexion of 20–45 degrees.[67] End-range flexion is resisted by the posterior half of annulus and by the impaction of the zygapophyseal joints.

According to Lee,[28] flexion of the cervicothoracic region consists of an anterior rotation of the head of the rib and a superoanterior glide of the zygapophyseal joints, whereas extension and arm elevation in this region consists of a posterior sagittal rotation and posterior translation of the superior vertebra. This latter action pushes the superior aspect of the head of the rib posteriorly at the costovertebral joint, producing a posterior rotation of the rib (the anterior aspect travels superiorly, while the posterior aspect travels inferiorly).[28]

In the remainder of the thorax, flexion results from the superior facets (i.e., the inferior articular processes of the superior vertebra of the segment) gliding superiorly and anteriorly (Table 27-3).[28] This motion at the zygapophyseal joint is accompanied by an anterior translation of the superior vertebra, and a slight distraction of the centrum. It seems likely that the anterior vertebral translation produces a similar motion in the ribs, with a superior glide occurring at the costotransverse joint. During this motion, the anterior aspects of the ribs approximate each other, while the posterior aspects separate.

Studies have shown that the thoracic zygapophyseal facets play an important role in stabilization of the thoracic spine during flexion loading.[58,68]

Extension

Extension of the thoracic spine is produced principally by the lumbar extensors and results in an inferior glide of the superior facet of the zygapophyseal joint (see Table 27-3). One to two degrees of extension is available at each thoracic segment, giving an overall average of 15–20 degrees of thoracic extension for the entire thoracic spine.

Extension of the thoracic spine is restrained by the relative stiffness of the anterior IVD; the anterior longitudinal ligament; bony contact of the posterior elements, including the inferior facet onto the lamina below; and the spinous processes.[23,58] Given the location of the axis of rotation of extension, which is close to the moving segment, more translation than rotation occurs during extension.[69]

The joint motions occurring with extension are essentially the opposite of those of flexion. The translation of the vertebra occurs in a posterior direction, with an accompanying slight compression of the centra. The posterior translation that occurs with extension is controlled by the posteriorly directed lamellae of the annulus, and by the capsule of the zygapophyseal joint.

The transitional region between the thoracic and lumbar spines can produce an inflexion point that may serve to reduce the bending forces in the sagittal plane.[6] However, stiffness in this area also may result in the thoracic spine pivoting over the thoracolumbar region, thereby increasing the risk of compression fracture (see Chapter 5).[70]

In addition to those motions occurring at the zygapophyseal joints and the vertebral body during thoracic extension, the motion also occurs at the rib articulations. The ribs rotate posteriorly, with the posterior aspects approximating and the anterior aspects separating, and an inferior glide occurs at the costotransverse joint.[28]

CLINICAL PEARL

Thoracic spine extension motion is considered important for normal shoulder girdle function, and an impairment of this movement may contribute to the development of subacromial impingement and shoulder pain.[71] Theoretically, facilitating extension motion in the thoracic spine may increase the acromiohumeral distance and range of arm elevation, and delay the onset of pain, in this population of patients. Indeed, short-and long-term benefits of thoracic spine manipulation have been described for the management of the shoulder impingement disorders.[72,73]

Side Bending

Side bending of the thoracic spine is initiated by the ipsilateral abdominals and erector muscles and then continued by gravity. A total of 25–45 degrees of side bending is available in the thoracic spine, at an average of about 3–4 degrees to each side per segment, with the lower segments averaging slightly more, at 7–9 degrees, each.[22,74]

At the zygapophyseal joints, the primary motion involves the ipsilateral superior facet gliding inferiorly, and the contralateral gliding superiorly (see Table 27-3). In effect, the

TABLE 27-3 Biomechanics of the Thorax

Motions	Z Joint	Rib Motion	Costotransverse Joint
Vertebromanubrial (T1–2)			
Flexion	Superoanterior glide	Anterior rotation	NA
Extension	Inferoposterior glide	Posterior rotation	NA
Latexion	Ipsilateral coupling	NA	NA
Rotexion	Ipsilateral coupling	NA	NA
Inspiration	NA	Elevation	NA
Expiration	NA	Depression	NA
Vertebrosternal (T3–7)			
Flexion	Superoanterior glide	Varies (very mobile) anteroposterior rotation	Superior–inferior glide (varies)
Extension	Posteroinferior glide	Varies (very mobile) anteroposterior rotation	Superior–inferior glide (varies)
Latexion	Ipsilateral side bend and contralateral rotation	Ipsilateral—anterior rotation Contralateral—posterior rotation	Ipsilateral—superior glide Contralateral—inferior glide
Rotexion	Ipsilateral side bend and ipsilateral rotation	Ipsilateral—posterior rotation Contralateral—anterior rotation	Ipsilateral—inferior glide Contralateral—superior glide
Inspiration	NA	Posterior rotation bilaterally	Inferior glide
Expiration	NA	Anterior rotation bilaterally	Superior glide
Vertebrochonral (T8–10)			
Flexion	Superoanterior glide	Anterior rotation	SMP glide
Extension	Inferoposterior glide	Posterior rotation	ILA glide
Latexion	Varies	NA	Apex in line with trochanter Ipsilateral—SMP Contralateral—ILA If not, the reverse occurs
Rotexion	Ipsilateral—inferior glide Contralateral—superior glide	NA	Ipsilateral—ILA, then anteromedial Contralateral—SMP, then posterolateral glide
Inspiration	NA	NA	ILA glide
Expiration	NA	NA	SMP glide

NA, not applicable; SMP, superior medial posterior; ILA, inferior lateral anterior.

ipsilateral zygapophyseal joint extends while the contralateral flexes. Side bending is restrained by the compression of the IVD and approximation of the ribs.

Side bending in the upper thoracic spine is associated with ipsilateral rotation and ipsilateral translation.[75] According to Lee,[28] the coupling that occurs in the rest of the thoracic spine depends on which of the two coupling motions initiates the movement. If side bending initiates the movement, it is called latexion, and the biomechanics consist of side bending, contralateral rotation, and ipsilateral translation. The mechanism of this coupling, or actually tripling, is not certain, and one must guard against strong conclusions. The postulated mechanism is as follows: with side bending, a contralateral convex curve is produced. This causes the ribs on the convex side of the curve to separate and those on the concave side to approximate.[28] Trunk side bending is essentially halted, by soft-tissue tension or rib approximation, or both, and the ribs become fixed. Further side bending is modified by the fixed ribs.[28] The ipsilateral articular facet of the transverse process glides inferiorly on its rib, resulting in a relative anterior rotation of the neck of the rib, while the contralateral transverse process glides superiorly, producing a posterior rotation of the rib neck.[28] The effect of these bilateral rib rotations is to force the superior vertebra into rotation away from the direction of side bending.

Rotation

The axis of rotation for the thoracic spine varies according to the vertebral level.[76] The axis of rotation lies within the vertebral body in the midthoracic joints, but anterior to the vertebral body in the upper and lower joints.[76] Almost pure rotation can occur in the midthoracic region, whereas, in the upper and lower segments, rotation can be associated with side bending to either side (see Table 27-3). Axial rotation (rotexion) is produced either by the abdominal muscles and other trunk rotators or by the unilateral elevation of the arm. Pure axial rotation (twisting) can only occur at two points in the spine: at the thoracolumbar and cervicothoracic junctions.

A total of 35–50 degrees of rotation is available in the thoracic spine.[22,74] Segmental axial rotation in the thoracic spine averages 7 degrees in the upper thoracic area, approximately 5 degrees in the middle thoracic spine, and 2–3 degrees in the last two or three segments.[22,67,77] Torsional stiffness is enhanced in the thoracolumbar region by the mortise-type morphology of the zygapophyseal joints and the near sagittal alignment of the upper lumbar articulations.[23,27,64,70,78]

According to MacConnail and Basmajian,[29] thoracic segmental rotation is coupled with contralateral side bending and contralateral translation. However, this finding deviates from what is generally observed clinically, where the coupling of rotation and side bending that occurs seems to depend on the segmental level and the integrity of the joint.

Respiration

T e ribs function as levers, with the fulcrum represented by the rib angle, the effort arm represented by the neck, and the load arm represented by the shaf . Because of the relatively small size of the rib neck, a small movement at the rib neck will produce a large degree of movement in the shaf .

T e shapes of the articular facets of the upper six ribs would suggest that the upward and downward gliding movements that occur would produce spinning of the neck of the rib. In fact, the main movement in the upper six ribs during respiration and other movements is one of the rotations of the neck of the rib, with only small amounts of superior and inferior motion. In the seventh through tenth ribs, the principal movement is upward, backward, and medially during inspiration, with the reverse occurring during expiration.[28]

Because the anterior end of the ribs is lower than the posterior, when the ribs elevate, they rise upward, while the rib neck drops down. In the upper ribs, this results in an anterior elevation (pump handle) and in the middle and lower ribs (excluding the free ribs), a lateral elevation (bucket handle), with the former movement increasing the anteroposterior diameter of the thoracic cavity and the latter increasing the transverse diameter (Fig. 27-5).

Both kinds of rib motion are produced by the action of the diaphragm. T e seventh through tenth ribs act to increase the abdominal cavity free space to afford space for the descending diaphragm. As the ends of these ribs are elevated, they push up on each other, lif ing each successive rib upward and finally lif ing the sternum. T e two lower ribs are depressed by the quadratus lumborum to provide a stable base of action for the diaphragm.

Quiet respiration involves very little zygapophyseal joint motion.

Inspiration

During inspiration, the diaphragm descends and pulls the central tendon inferiorly through the fixed 12th ribs and L1–3 (Fig. 27-6). When the maximum extensibility (distention) of the abdominal wall is reached, the central tendon becomes stationary. Further contraction of the diaphragm produces an elevation and posterior rotation of the lower six ribs, with torsion of the anterior costal cartilage, and an anterosuperior thrust of the sternum (and eventually the inferior aspect of the manubrium).

During inspiration in the normal population, because the second rib is longer than the first, the superior aspect of the manubrium is forced to tilt posteriorly as its inferior edge is moved anteriorly. As the top of the manubrium tilts back, the clavicle rolls anteriorly. Because the lower ribs are longer, the inferior sternum moves further anteriorly than the superior section during inspiration. T e manubriosternal junction acts as the hinge for this motion. If this joint stiffens or ossifies, respiratory function will suffer. In addition, if the central tendon stiffens, inspiration will have to be accomplished, with the ribs moving laterally.

Forced inspiration produces an increase in the activity level of the diaphragm, intercostals, scaleni, and quadratus lumborum. In addition, new activity occurs in the sternocleidomastoid, trapezius, both pectorals and serratus anterior.

During inspiration, the ribs move with the sternum in an upward and forward direction, increasing the anteroposterior diameter of the chest while posteriorly rotating. T e tubercles and costotransverse joints of[28]

- T1–7 glide inferiorly;
- T8–10 glide in an anterolateral and inferior direction; and
- T11 and T12 remain stationary, except for slight caliper motion increasing the lateral dimension.

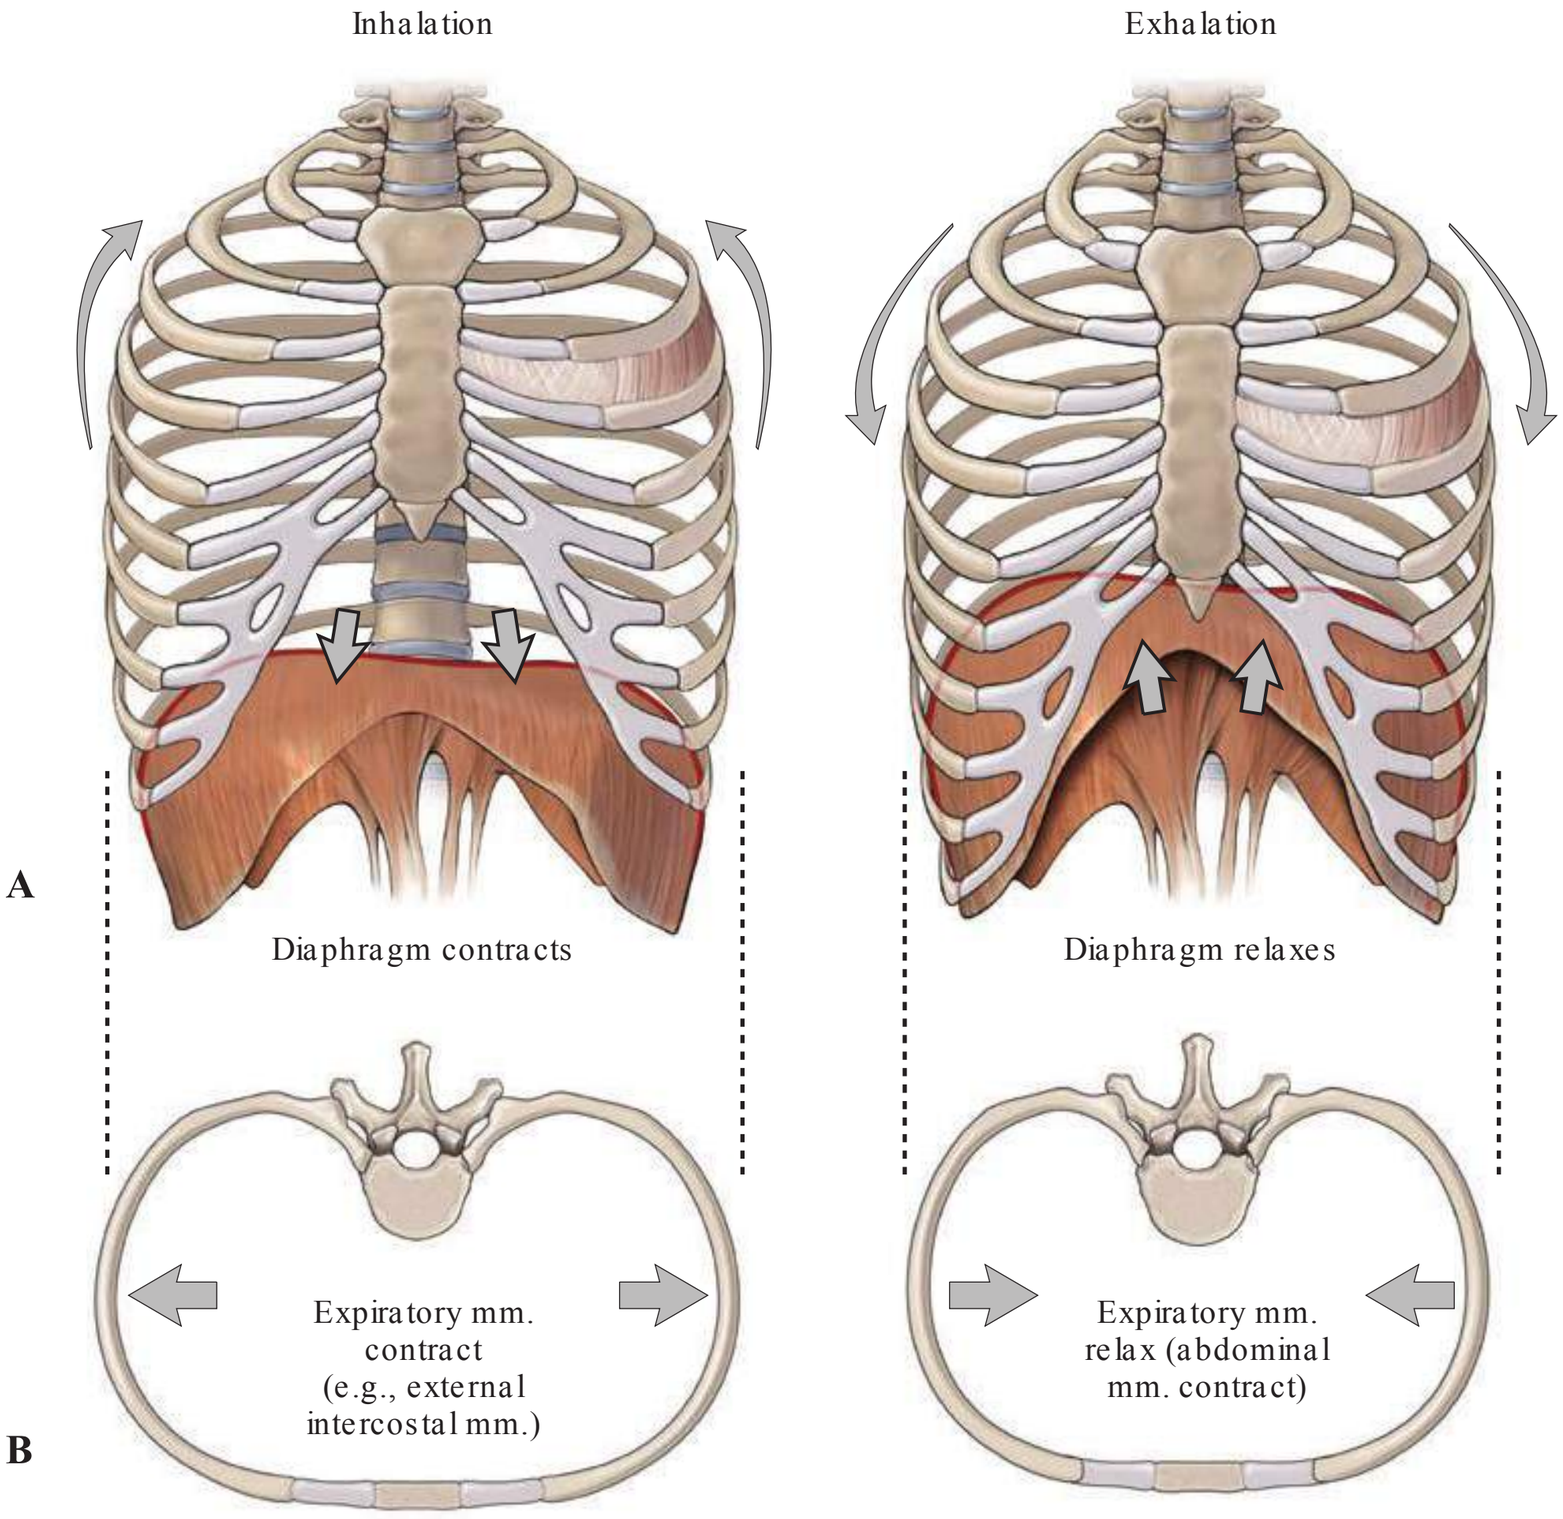

FIGURE 27-6 Biomechanics of respiration. (Reproduced, with permission, from Chapter 3. Lungs. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Expiration

Quiet expiration occurs passively (Fig. 27-6). During forced expiration, there is activity in a number of muscles (Table 27-1). During expiration, the ribs rotate anteriorly and the tubercles and costotransverse joints of[28]

- T1–7 glide superiorly;
- T8–10 glide in a posteromedial and superior direction; and
- T11 and T12 remain stationary, except for slight caliper motion decreasing the lateral dimension.

It may be possible to detect a subluxation of the costotransverse joints by palpating the ipsilateral transverse process and rib during inspiration and thoracic side bending.[28] For example, a superior subluxation of the right rib may produce the following:

- A decreased inferior glide of the rib
- A decreased thoracic motion in the directions of lef side bending and right rotation

T e findings for other rib dysfunctions are outlined in Table 27-4.

TABLE 27-4 Rib Dysfunctions

Dysfunction	Rib Angle	Intercostal Space	Anterior Rib	Thoracic Findings
Anterior subluxation	Less prominent	Tender	NA	More prominent
Posterior subluxation	More prominent	Tender	NA	Less prominent
External rib torsion	Prominent and tender superior border	Wide above and narrow below	ERS, ipsilateral at the level above	NA
Internal rib torsion	Prominent and tender inferior border	Narrow above and wide below	FRS, contralateral at the level above	NA

ERS, extended, rotated, and side flexed; FRS, flexed, rotated, and side flexed; NA, not applicable.

EXAMINATION

Differential diagnosis of thoracic pain can be difficult. T is is due to the complicated biomechanics and function of the region, the proximity to vital organs, and the many articulations. Bogduk[79] has cited the following anatomical structures as possible causes of thoracic spine pain: posterior thoracic muscles, spinous processes, anterior and posterior longitudinal ligaments, vertebral bodies, zygapophyseal and costotransverse joints, inferior articular process, pars interarticularis, IVD, nerve root, joint meniscus, and dura mater. Pain arising from inflammation of the axial spine can mimic a variety of serious conditions, including cardiac/pulmonary pathology, renal colic, fracture, a tumor, or numerous visceral and retroperitoneal abnormalities, including abdominal aortic aneurysm.[80]

T e thoracic spine is less commonly implicated in musculoskeletal pain syndromes than the lumbar and cervical spines, and when it does occur, there is some disagreement as to whether the ribs or the intervertebral joints are the major sources of the biomechanical dysfunction. Complicating matters is the fact that pain arising from the thoracic spinal joints has considerable overlap and can refer symptoms to distal regions (groin, pubis, and lower abdominal wall) (refer to Chapter 5). Apart from musculoskeletal lesions, the thoracic spine is also a common source of systemic pain, and the phenomenon of referred pain poses more diagnostic difficulties in the thoracic spine than in any other region of the vertebral column (Fig. 27-7).[79] T e algorithm outlined in Figure 27-8 can serve as a guide to the examination of the thoracic spine and ribs.

History

T e history should include the chief complaints and a pain drawing. Referred chest pain patterns are outlined in Table 27-5. In addition to those questions listed under History in Chapter 4, the following questions should be asked by the clinician:

- Was there a mechanism of injury? Any information regarding the onset is important. For example, most rib injuries are commonly caused by direct trauma. If there was no mechanism of injury, a disease process such as scoliosis could be indicated. Costovertebral and costotransverse joint hypomobility and active trigger points are possible sources of upper thoracic pain.[81]
- Do the symptoms occur with breathing? Symptoms reproduced with respiration could indicate a rib dysfunction or pleuritic pain. If the symptoms are aggravated on exertion, the clinician should focus on the relationship of specific movements or activities. Any information regarding the onset, as well as aggravating factors, is important, especially if the pain appears only during certain positions or movements, which would suggest a musculoskeletal lesion. Deep breathing or arm elevation tends to aggravate a rib dysfunction.
- Are the symptoms provoked or alleviated with movement or posture? T is type of history indicates a musculoskeletal dysfunction. Chronic problems in this area tend to result from postural dysfunctions. T e pain of a mechanical origin tends to worsen throughout the day but is relieved with rest.
- What activities tend to aggravate the symptoms? Pulling and pushing activities typically worsen thoracic symptoms. Aggravation of localized pain by coughing, sneezing, or deep inspiration tends to implicate the costovertebral joint.[82]
- Is the pain deep, superficial, aching, burning, or stabbing? T e patient is asked to describe the quality of the pain. T oracic nerve root pain is of en sharp, stabbing, and severe, although it can also have a burning quality. Nerve pain usually is referred in a sloping band along an intercostal space.[20] Vascular pain and visceral pain of en are described as being poorly localized and achy. A sudden onset of pain related to trauma could indicate a fracture, muscle strain, or ligament sprain.

CLINICAL PEARL

Pain from a musculoskeletal lesion in this area can vary from a dull ache to a feeling of local fatigue and cramping. Muscular pain is usually sharp and well localized, whereas tendon pain is typically dull and aching. Bone pain usually feels very deep and boring.

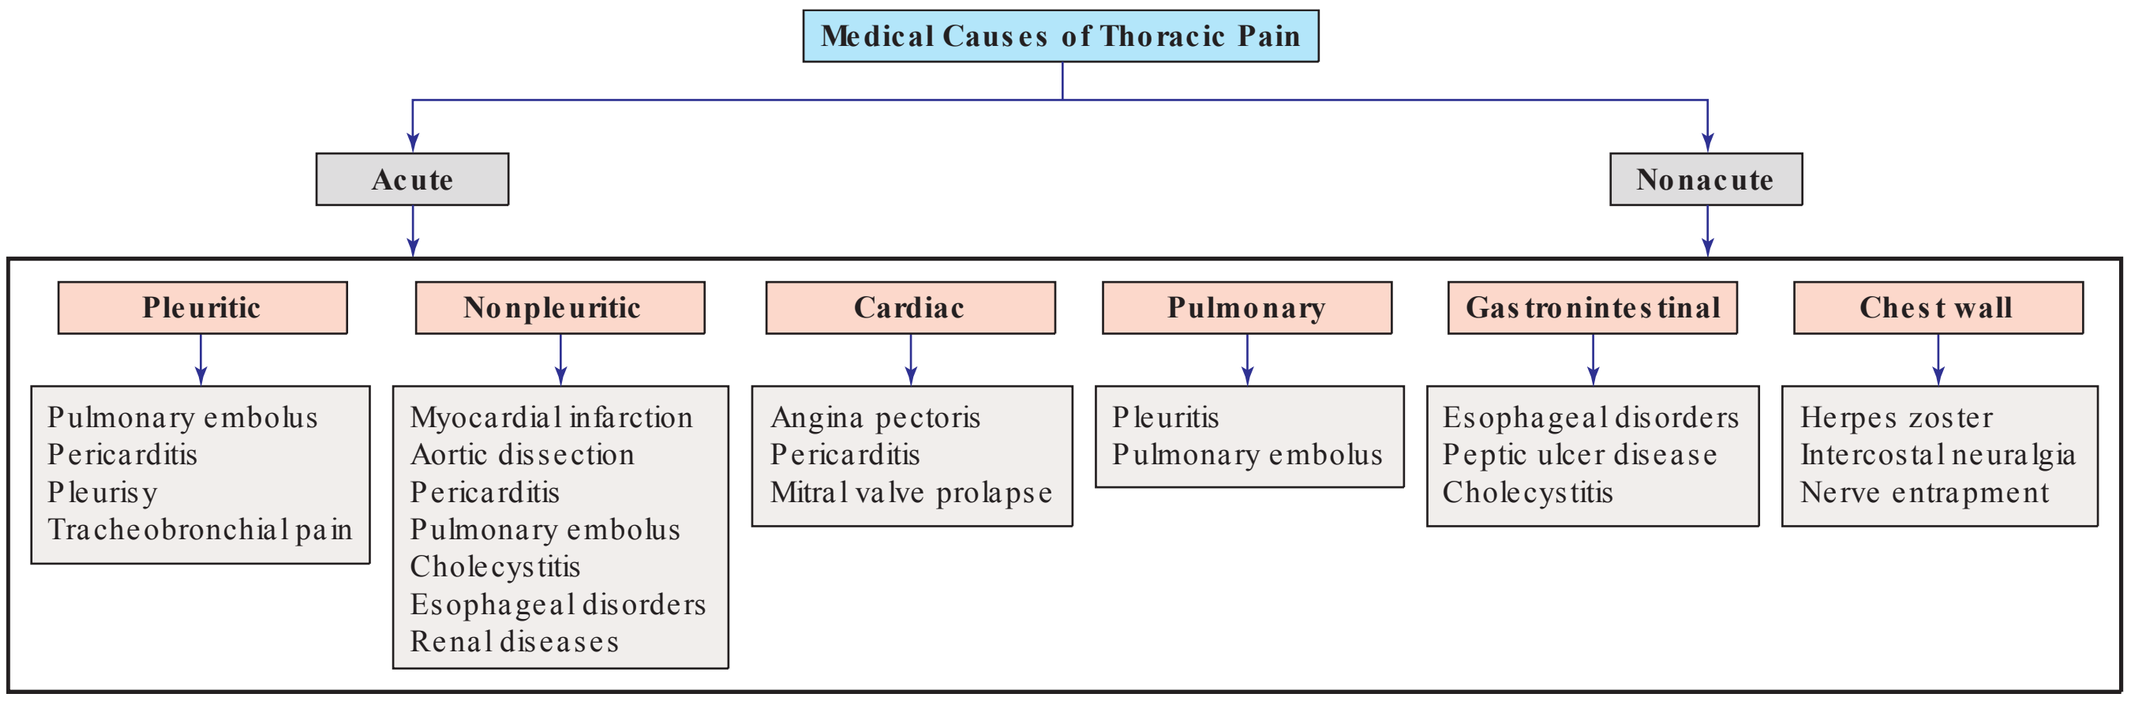

FIGURE 27-7 Medical causes of thoracic symptoms.

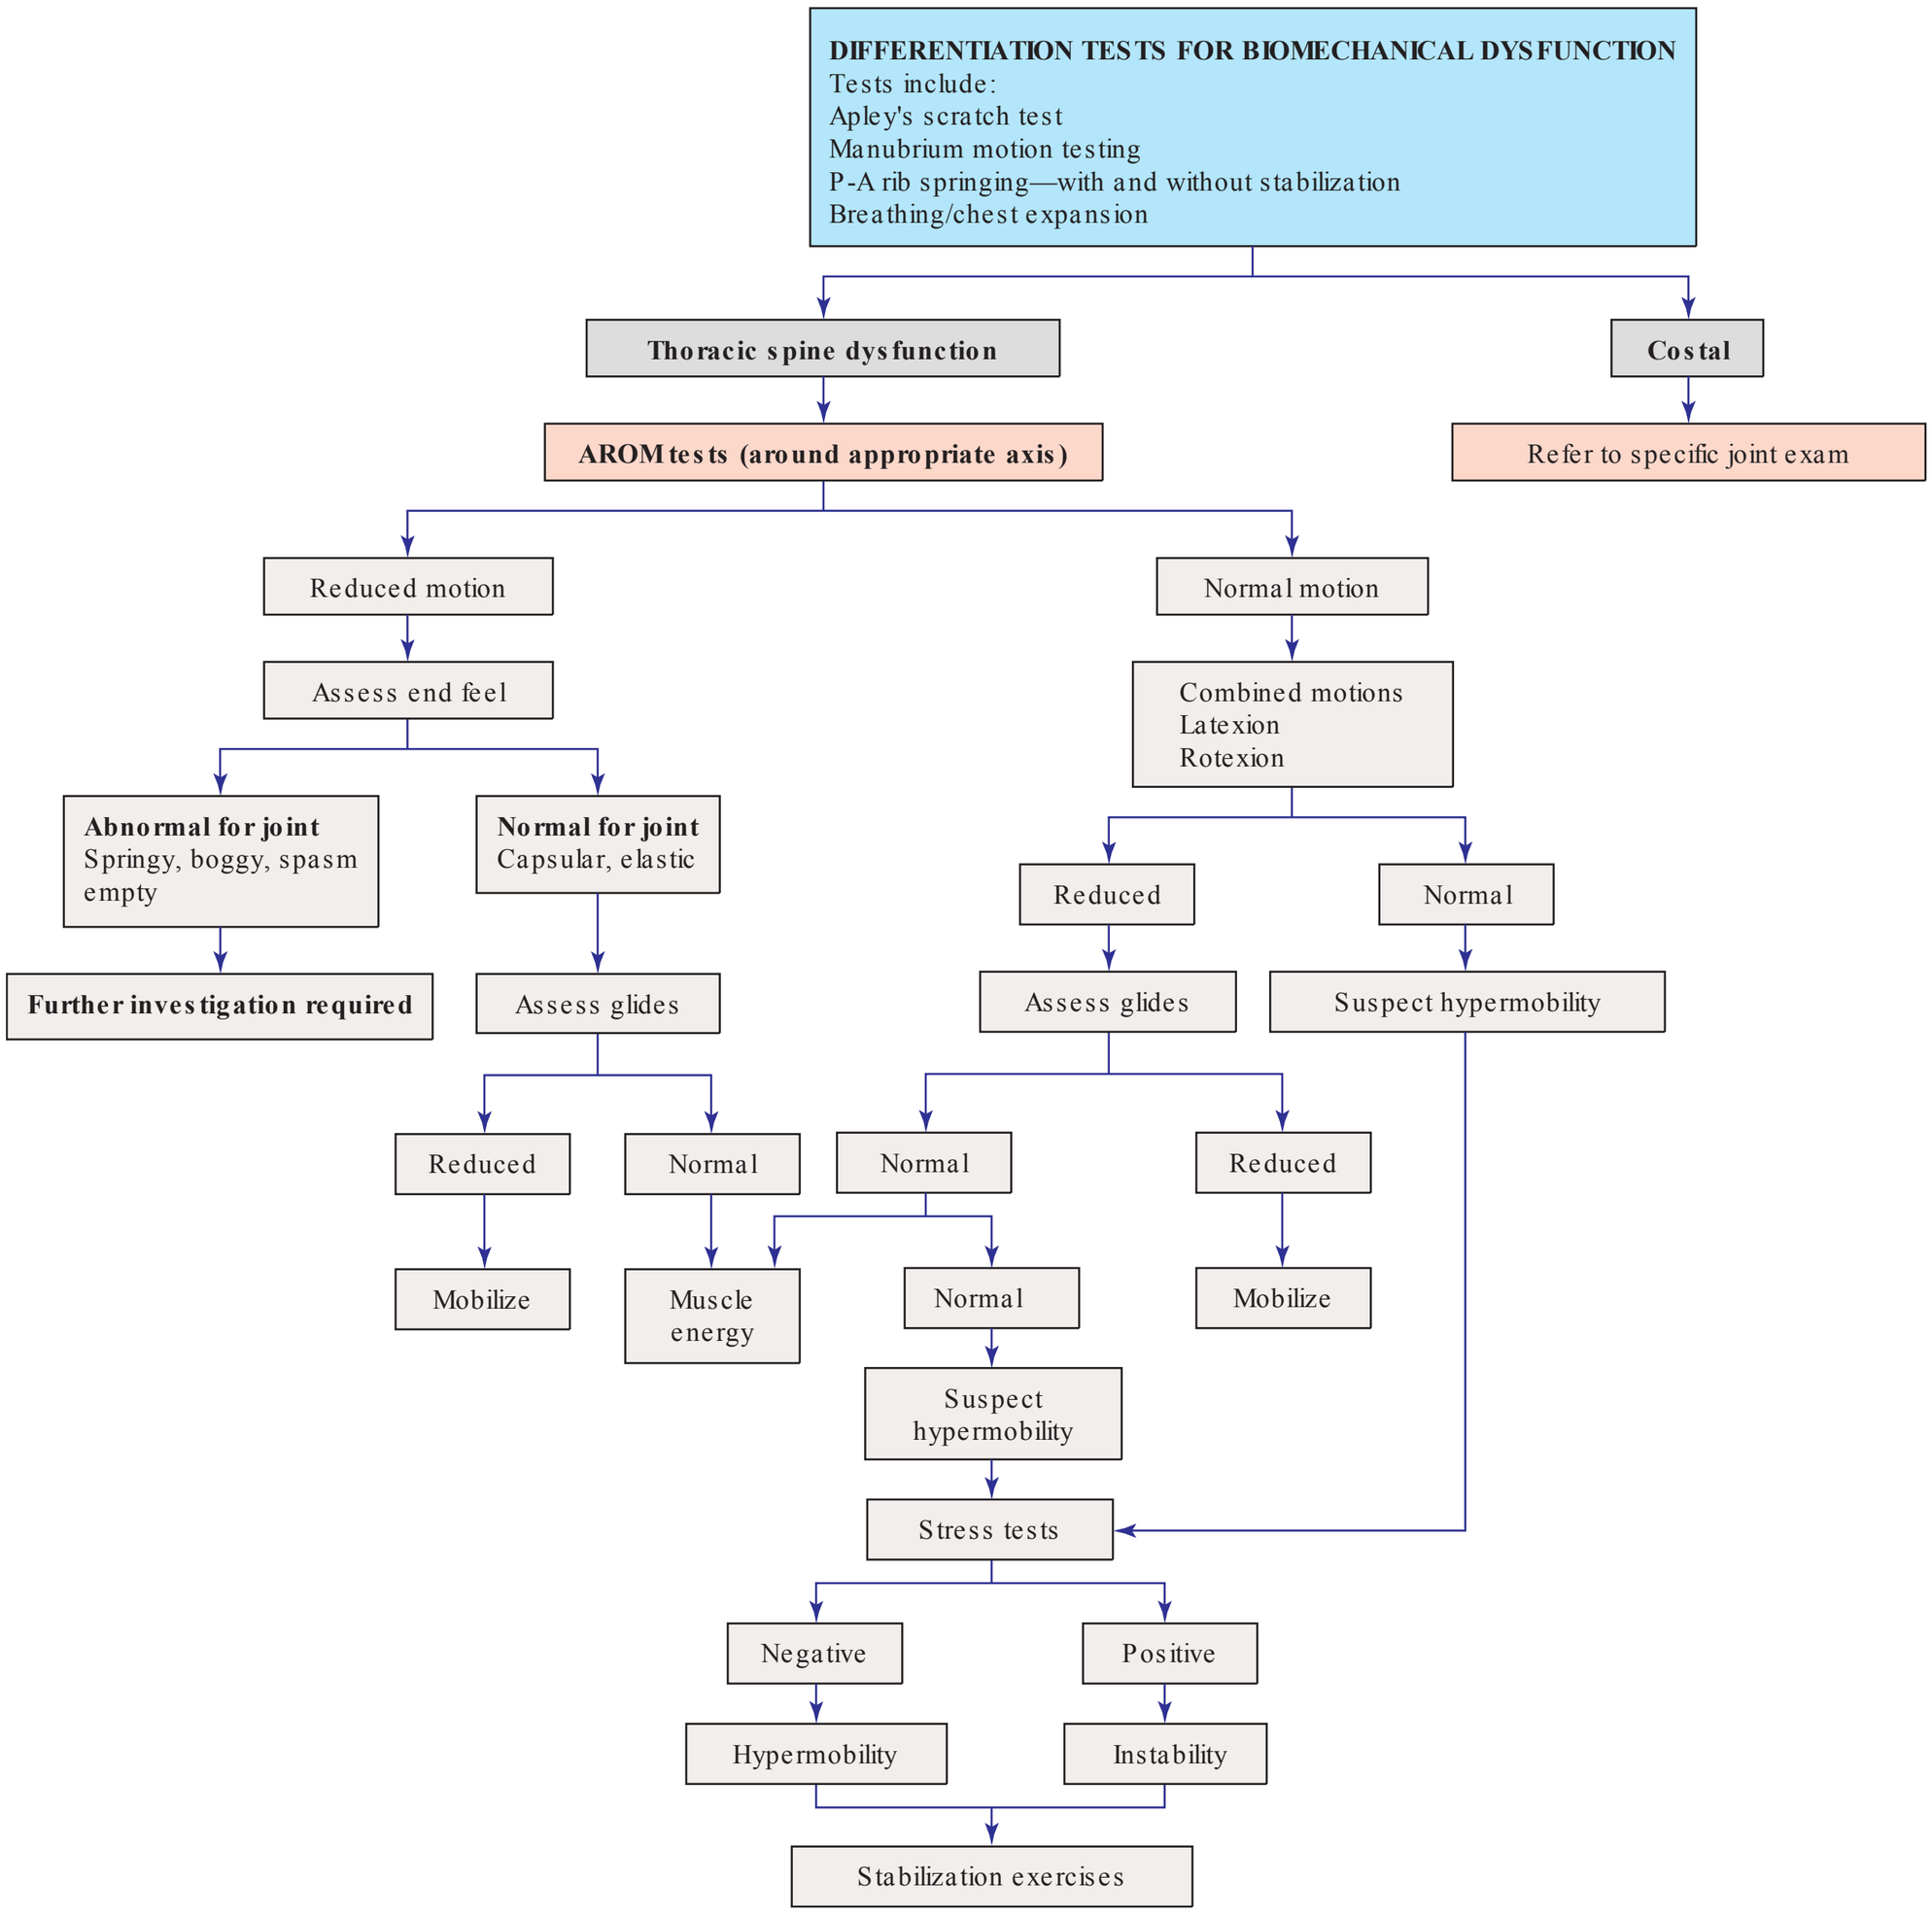

FIGURE 27-8 Thoracic spine examination algorithm.

- Where is the pain located? The patient should be asked to point to the area of pain. If the patient has difficulty localizing the pain, the clinician should suspect referred pain as the source. If the symptoms appear to be referred to the upper or lower extremities, or the head and neck, further investigation is required.
- Are the symptoms related to digestion? Some visceral conditions such as ulcers, can be referred to T4–6 posteriorly.

The administration of the Oswestry Low Back Disability Questionnaire (Table 5-2), Neck Disability Index (Table 5-3), and McGill Pain Questionnaire (Chapter 4) may be helpful in determining the quality of pain and its effect on function.[83–85]

Systems Review

Thoracic pain may originate from just about all of the viscera (Table 27-6; see also Chapter 5). Both visceral and somatic afferent nerves transmit pain messages from a peripheral stimulus and converge on the same projection neurons in the posterior (dorsal) horn. Visceral pain tends to be vague and dull and may be accompanied by nausea and sweating (see Chapter 5). To help differentiate between visceral pain and musculoskeletal pain, the clinician should focus on the relationship of specific movements or activities. A medical screening questionnaire for the thoracic spine and rib cage region is provided in Table 27-7.

The thoracolumbar outflow of the autonomic nervous system (see Chapter 3) has its location here. Stimulation of this outflow can lead to the presence of facilitated segments, and trophic changes in the skin of the periphery.[86]

Systemic illnesses, such as rheumatoid arthritis and malignancy, and conditions causing referred pain must be included in the differential diagnosis. Nonmusculoskeletal causes of thoracic pain (Table 27-8) include the following[87]:

- Dissecting aortic aneurysm.
- Myocardial infarction.

TABLE 27-5 Chest Pain Patterns

Origin of Pain	Site of Referred Pain	Type of Disorder
Substernal or retrosternal	Neck, jaw, back, left shoulder and arm, and abdomen	Angina
Substernal, anterior chest	Neck, jaw, back, and bilateral arms	Myocardial infarction
Substernal or above the sternum	Next, upper back, upper trapezius, supraclavicular area, left arm, and costal margin	Pericarditis
Anterior chest (thoracic aneurysm); abdomen (abdominal aneurysm)	Posterior thoracic, chest, neck, shoulders, interscapular, or lumbar region	Dissecting aortic aneurysm
Variable	Variable, depending on structures involved.	Musculoskeletal
Costochondritis (inflammation of the costal cartilage): sternum and rib margins.	Abdominal oblique trigger points: pain referred up into the chest area.	
Upper rectus abdominis trigger points (left side), pectoralis, serratus anterior, and sternalis muscles: precordial pain	Pectoralis trigger points: pain referred down medial bilateral arms along ulnar nerve distribution (fourth and fifth fingers)	
Precordium region (upper central abdomen and diaphragm)	Sternum, axillary lines, and either side of vertebrae; lateral and anterior chest wall; occasionally to one or both arms	Neurological
Substernal, epigastric, and upper abdominal quadrants	Around chest area, shoulders, and upper back region	Gastrointestinal
Within breast tissue; may be localized in pectoral and supraclavicular regions	Chest area, axilla, mid-back, and neck and posterior shoulder girdle	Breast pain
Commonly substernal and anterior chest region	No referred pain	Anxiety

TABLE 27-6 Symptoms and Possible Causes of Thoracic Pain

Indication	Possible Condition
Severe bilateral root pain in elderly	Neoplasm (most common areas for metastasis are lung, breast, prostate, and kidney)
Wedging/compression fracture	Osteoporotic (estrogen deficiency) or neoplastic fracture
Onset–offset of pain unrelated to trunk movements	Ankylosing spondylitis, visceral
Decreased active motion: contralateral side flexion painful, with both rotations full	Neoplasm
Severe chest wall pain without articular pain	Visceral
Spinal cord signs and symptoms	Spinal cord pressure or ischemia
Pain onset related to eating or diet	Visceral

TABLE 27-7 Medical Screening Questionnaire for the Thoracic Spine and Rib Cage Region

	Yes	No
Do you have a history of heart problems?		
Have you recently taken a nitroglycerin tablet?		
Do you take medication for hypertension?		
Have you been or are you now a smoker?		
Have you had a recent surgery?		
Have you recently been bedridden?		
Have you recently noticed that it is dif cult for you to breathe, laugh, sneeze, or cough?		
Have you recently had a fever, infection, or other illness?		
Have you recently received a blow to the chest, such as during a fall or motor vehicle accident?		
Are your symptoms relieved after eating?		
Does eating fatty food increase your symptoms?		
Do you currently have a kidney stone or have you had one in the past?		
Do you experience severe back or flank pain that comes on suddenly?		

Data from DuVall RE, Godges J. Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. Medical Screening *for* the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1. La Crosse, WI: Orthopaedic Section, APTA, Inc; 2003:1–44.

TABLE 27-8 Red Flags for the Thoracic Spine and Rib Cage

Condition	Red Flags
Myocardial infarction	Chest pain Pallor, sweating, dyspnea, nausea, or palpitations Presence of risk factors: previous history of coronary heart disease, hypertension, smoking, diabetes, and elevated blood serum cholesterol (> 240 mg/dL) Men aged over 40 years and women aged over 50 years Symptoms lasting greater than 30 min and not relieved with sublingual nitroglycerin
Stable angina pectoris	Chest pain or pressure that occurs with predictable levels of exertion (if not, suspect unstable angina pectoris) Symptoms are also predictably alleviated with the rest or sublingual nitroglycerin (if not, suspect unstable angina pectoris)
Pericarditis	Sharp or stabbing chest pain that may be referred to the lateral neck or either shoulder Increased pain with left side lying Relieved with forward lean while sitting (supporting arms on knees or a table)
Pulmonary embolus	Chest, shoulder, or upper abdominal pain Dyspnea
Pleurisy	Severe, sharp knife-like pain with inspiration History of a recent or coexisting respiratory disorder (e.g., infection, pneumonia, tumor, or tuberculosis)
Pneumothorax	Chest pain that is intensified with inspiration, ventilation, or expanding rib cage Recent bout of coughing or strenuous exercise or trauma Hyperresonance upon percussion Decreased breath sounds
Pneumonia	Pleuritic pain that may be referred to shoulder Fever, chills, headache, malaise, or nausea Productive cough
Cholecystitis	Colicky pain in the right upper abdominal quadrant with accompanying right scapula pain Symptoms may worsen with ingestion of fatty foods Symptoms unaffected by activity or rest
Peptic ulcer	Dull, gnawing pain, or burning sensation in the epigastrium, midback, or supraclavicular regions Symptoms relieved with food Localized tenderness at the right epigastrium Constipation, bleeding, vomiting, tarry colored stools, and coffee ground emeses
Pyelonephritis	Recent or coexisting urinary tract infection Enlarged prostate Kidney stone or past kidney stone
Nephrolithiasis (kidney stones)	Sudden, severe back, or flank pain Chills and fever Nausea or vomiting Renal colic Symptoms of urinary tract infection Reside in hot and humid environment Past episode(s) of kidney stone(s)

- Intercostal neuralgia.
- Pleural irritation: When the tissues of an irritated pleura are stretched, chest pain can result. T is pain can be increased by breathing, as well as by trunk movements, a situation that could lead the clinician to believe that the problem is musculoskeletal.
- Tumor.
- Acute thoracic disk herniation.
- Unstable or stable angina pectoris.
- Pericarditis.
- Pneumothorax.
- Pneumonia.
- Cholecystitis.
- Peptic ulcer.
- Pyelonephritis.
- Nephrolithiasis (kidney stones).

Questions should be asked with regard to bowel and bladder function; upper and lower extremity numbness, tingling, or weakness; and visual or balance disorders. T ese symptoms may indicate compromise to the spinal cord, cauda equina, or central nervous system.

Questions must also be asked about unexplained weight loss, fever, chills, and night pain. T ese symptoms of en are associated with cancer or systemic disease, although night pain may just be because the patient has an increased, and fixed, kyphosis and needs a sof er bed to accommodate the deformity.[88]

Tests and Measures

Observation

T e patient should be suitably disrobed to expose as much of this region as is necessary. As a quick orientation to the relationship of the bony structures (Fig. 27-1), the clinician should confirm the following findings:

- T e spine of the scapula is level with the spinous process of T3.
- T e inferior angle of the scapula is in line with the spinous processes of T7–9.
- T e medial border of the scapula is parallel with the spinal column and about 5 cm lateral to the spinous processes.
- T e iliac crests are level and symmetric. One crest higher than the other could suggest a leg-length discrepancy, an iliac rotation, or both.
- T e shoulder heights are level. A normal variant is that individuals carry their dominant shoulder slightly lower than the nondominant side.

T e clinician also should evaluate the following:

- T e smoothness of the thoracic curve: By running the palm of the hand down the midline of the patient's thoracic spine, the clinician can determine the smoothness of the curvature. Any areas of flatness could suggest a vertebral dysfunction such as an opening restriction (extended, rotated, and side-flexed [ERS] lesion) whereas areas of relative increased curvature suggest a closing restriction (flexed, rotated, and side-flexed [FRS] lesion); refer to Chapter 25.
- T e degree of thoracic kyphosis: As elsewhere in the spine, posture has an important influence on the available range of motion of the neighboring joints. Conversely, changes in the lumbar posture, such as excessive lordosis, and changes in the cervical spine, such as those rendered by a forward head position, can affect the thoracic spine. An increased lumbar lordosis increases the stresses applied to the thoracolumbar junction, whereas a forward head increases the stresses at the cervicothoracic junction.

T e thoracic spine adopts a natural kyphotic curve, which is an increased convexity of the thoracic vertebrae. Varying degrees of kyphosis can occur in the thoracic spine. It is known that the thoracic kyphosis increases with age,[89] and in women more than men.[90] T e appearance of increased kyphosis in the young is typically postural, but could be the result of Scheuermann's disease, or ankylosing spondylitis (see Chapter 5).[23,91] T e degree of curvature of the spine also has been found to be diurnal, with a slight flattening of the thoracic kyphosis occurring overnight.[92] Attempts to define the "normal" thoracic kyphosis have demonstrated considerable variation in the asymptomatic population,[63,93] suggesting that any individual differences reflect normal variations rather than deviations.

It has been theorized by a number of authors[94–99] that postural dysfunctions in this region create an imbalance between agonists and antagonists, producing adaptive shortening and weakness. It is likely that these changes are degenerative in nature, resulting from a change in IVD height. Disk height changes commonly are seen in the upper midthoracic segments[100] and may result in an alteration of the kyphotic curve, with subsequent compensatory changes in load bearing and movement. T ese altered load-bearing patterns may result in a compression of the anterior aspect of the thoracic IVDs, and a stretching of the thoracic extensors and the middle and lower trapezius. T e posterior ligaments also are lengthened. In addition, the kyphotic posture is associated with adaptive shortening of the anterior longitudinal ligament, the upper abdominals, and the anterior chest muscles. T e common kyphotic deformities include[101]:

- Dowager's hump: T is deformity is characterized by a severely kyphotic upper posterior (dorsal) region, which results from multiple anterior wedge compression fractures in several vertebrae of the middle to upper thoracic spine (see Chapter 5), usually caused by postmenopausal osteoporosis or long-term corticosteroid therapy (specificity, 0.99).[102]
- Hump back: T is deformity is a localized, sharp, posterior angulation, called gibbus, produced by an anterior wedging of one of the two thoracic vertebrae as a result of infection (tuberculosis), fracture, or congenital bony anomaly of the spine.[91]
- Round back: T is deformity is characterized by decreased pelvic inclination and excessive kyphosis.
- Flat back: T is deformity is characterized by decreased pelvic inclination, increased kyphosis, and a mobile thoracic spine.

- Pelvic heights: A significant leg-length discrepancy (greater than 1/2 in) can alter the lateral curvature of the spine, resulting in compensation.
- T e amount of lateral curvature of the thoracic spine: When observing the thoracic spine, it is important to note the morphologic latitude of the spinal curvature (see Chapter 6).[103]
- Chest wall shape: On the anterior aspect of the thoracic region, the clinician should look for evidence of deformity.
- Barrel chest: In this deformity, a forward and upward projecting sternum increases the anteroposterior diameter. T e barrel chest results in respiratory difficulty, stretching of the intercostal and anterior chest muscles, and adaptive shortening of the scapular adductor muscles.
- Pigeon chest: In this deformity, a forward and downward projecting sternum increases the anteroposterior diameter. T e pigeon chest results in a lengthening of the upper abdominal muscles and an adaptive shortening of the upper intercostal muscles.
- Funnel chest: In this deformity, a posterior-projecting sternum occurs secondary to an outgrowth of the ribs.[104] T e funnel chest results in adaptive shortening of the upper abdominals, shoulder adductors, pectoralis minor, and intercostal muscles, and in lengthening of the thoracic extensors and middle and upper trapezius.
- T e motion of the ribs during quiet breathing.
- Any asymmetry in muscle bulk, prominence, or length.

According to Sahrmann,[105] shortness of the rectus abdominis results in anterior rib cage depression, shortness of the internal oblique results in an increase in the infrasternal angle, and shortness of the external oblique results in a decreased angle. Rotatores atrophy could suggest nerve palsy whereas rotatores hypertonicity could suggest a segmental facilitation.[98,106]

- Any lesions, swellings, or scars on the back and chest: T is is a common area for the characteristic lesion pattern of herpes zoster (shingles), which follows the course of the affected nerve (see Chapter 5).

Gait

T e analysis of the patient's gait pattern can provide valuable information as to whether the condition originates in the spine or lower extremities, resulting in gross weakness of the muscles that affect gait[91] (see Chapter 6). For example, a decreased arm swing during gait can indicate stiffness of the thoracic segments.

Palpation

T e spinous processes of the thoracic vertebrae are readily palpated (see Fig. 27-1) because they are not covered by muscle or thick connective tissue.[91] Due to their depth relative to the more superficial structures of the spine, palpation of the thoracic transverse processes is more difficult. T e landmarks outlined in Table 27-9 may be helpful to determine the segmental level involved.

T e spinous processes are long and slender and have varying degrees of caudal obliquity, which changes slightly throughout the kyphotic curvature of the thorax, increasing in caudal angulation to the level of T7 and then decreasing in caudal angulation below T9. Traditionally, palpation of this area has utilized the "rule of threes."

TABLE 27-9 Anterior and Posterior Palpation Points of the Thoracic Region

Anterior Aspect	Posterior Aspect
Suprasternal notch	Spinous and associated transverse processes
Manubriosternal angle	T2—level with base of spine of scapula
Xiphoid process	Spinal gutter (rotatores)
Infrasternal angle	Erector spinae
Sternochondral junctions	Rib angles
Costal cartilage	Rib shafts and rib joint line of costotransverse joint C6—locate largest spinous process at base of neck and have patient extend neck; first spinous process to move anteriorly under your finger is C6

CLINICAL PEARL

The areas of spinous process obliquity may be divided into four regions by the so-called rule of three devised by Mitchell[107] (an alternate version is illustrated in Fig. 27-9).

- The upper three spinous processes (T1–3). The tips of these spinous processes are level with the vertebral body of the same level.
- The second group of three spinous processes (T4–6). The tips of these spinous processes are in a plane that is half way between its own transverse process and those of the inferior vertebra (level with the IVD of the inferior level). This can be estimated at about three fingerbreadths.
- The third group of three spinous processes (T7–9). The tips of these spinous processes are level with the transverse processes of the vertebral body of the level below.
- The last three vertebrae (T10–12) reverse the obliquity of the spinous processes:
- T10 is level with the vertebral body of the vertebra below (same as T7–9).
- T11 is level with the disk of the inferior vertebra (same as T6).
- T12 is level with its own vertebral body (same as T3).

T e rule of threes has been widely accepted in orthopaedic and manual therapy texts, but until recently, never validated with research. Based on a pilot study to investigate the validity of the rule of threes of the thoracic spine, Geelhoed et al.,[108] using five cadaver specimens, determined that the rule of threes was not an accurate predictor of the location of the

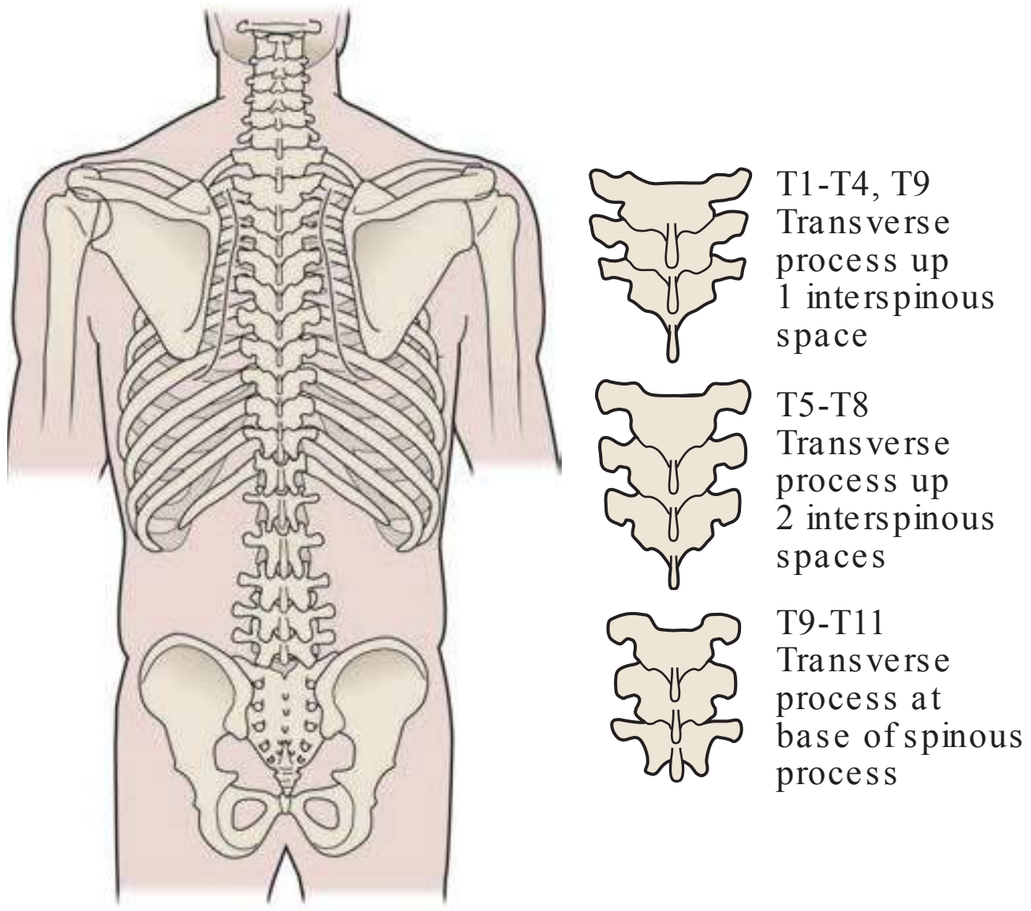

FIGURE 27-9 The rule of threes.

transverse processes of the thoracic spine. The limitations of the study were the small sample size, the fact that measurements were only performed in the horizontal plane (prone position), and the fact that cadavers were used instead of live subjects, which could affect IVD height and spinal alignment. In a separate study, Geelhoed et al.[109] have proposed a new model for predicting the location of the transverse processes of the thoracic spine. This is proposed method states that the location of the transverse processes of a thoracic vertebra can be found lateral to the most prominent aspect of the spinous process of the vertebra one level above.[109]

Surface landmarks can be used to locate the ribs. The first rib is located 45 degrees medially to the junction of the posterior scalene and trapezius. Palpation of the first rib during respiration can detect the presence of asymmetry. Palpation of the first rib can also be performed during testing of the active motions of cervical rotation and side bending in patients with suspected brachialgia (see Chapter 25).

The fifth rib passes directly under, or slightly inferior to, the male mammary nipples. To palpate the rib angles of the interscapular ribs, the shoulders are positioned in horizontal adduction. The rib angles of 3–10 can then be felt about 2–5 cm lateral to the spinous processes.

When palpating anteriorly, on the sternum, a rib dysfunction will be highlighted by the presence of asymmetry and should be compared with the posterior findings. A prominent rib angle on the back and a depression of that rib at the sternum indicate a posterior subluxation, the reverse occurring in an anterior subluxation, whereas a rib that is prominent both anteriorly and posteriorly indicates a single rib torsion.

The transverse processes are roughly level with their own body. The costal cartilages of the second rib articulate with the junction between the sternum and manubrium (Fig. 27-1).

Palpation of the soft tissues of the region is important. The clinician should note the presence of any tenderness, temperature changes, and muscle spasm. A comparison should be made between the firmness and tenderness of the paravertebral muscles and their relationship from side to side.

Active Motion Testing

Active range-of-motion tests are used to determine the osteokinematic function of two adjacent thoracic vertebrae during active motions, to identify which joints are dysfunctional, as well as the specific direction of motion loss.[110] Active range of motion initially is performed globally, looking for abnormalities, such as asymmetric limitations of motion. A specific examination is then performed on any region that appears to have either excessive or reduced motion. If the history indicated that the patient's symptoms were altered with repetitive motions or sustained positions, these movements and postures should be included. Various techniques are used to assess each area of the thoracic spine.

Movement restriction of the upper thoracic spine may be secondary to pain or a result of adaptive shortening of connective tissue or muscle.[3] Because of the relationship that the first two ribs share with the zygapophyseal joints as part of the manubrial ring, associated movement dysfunction of these ribs is common. Physiologic movement in the thoracic spine decreases with age. Midthoracic hypomobilities are the most common thoracic presentation,[111] with the movement restrictions being more common in the sagittal and frontal planes, particularly extension, and side bending.[3] Most of the trunk rotation below the level of C2 occurs in the thoracic spine.

The clinician should look for capsular or noncapsular patterns of restriction, pain, or painful weakness (possible fracture or neoplasm). The capsular pattern of the thoracic spine appears to be a symmetric limitation of rotation and side bending, extension loss, and least loss of flexion. Joint capsular lesions demonstrate a capsular pattern as an equal and grossly severe limitation of movement in every direction.[91] With an asymmetric impairment, such as trauma, the capsular pattern appears to be an asymmetric limitation of rotation and side bending, extension loss, and a lesser loss of flexion.

Overpressure applied at the end of the available range of motion is used to take the joint from its physiologic barrier to its anatomic barrier. During overpressure, an increase in resistance to motion should be felt. The end-feels should be noted.

- If the normal elastic end-feel of thoracic rotation is replaced by a stiffer one, it may indicate the presence of osteoporosis or ankylosing spondylitis (see Chapter 5).
- During forward flexion, nonstructural scoliosis disappears, whereas structural scoliosis does not.
- If side bending is more seriously affected than rotation, neoplastic disease of the viscera or chest wall may be present.[88]
- If, during side bending, the ipsilateral paraspinal muscles demonstrate a contracture (Forestier's bowstring sign), ankylosing spondylitis may be present.[112]
- Sidebending away from the painful side, which is the only painful and limited movement, almost always indicates a severe extraarticular impairment, such as a pulmonary or abdominal tumor or a spinal neurofibroma. The functional examination normally confirms the patient history.
- A marked restriction of motion in a noncapsular pattern with one or more spasmodic end-feels could indicate a thoracic disk herniation.

- Anterior or lateral pain with resisted thoracic rotation could indicate a muscle tear. Localized pain with resisted testing could indicate a rib fracture.

Because of the length of the spine in this region, it is important to ensure that all parts of the thoracic spine are involved in the range-of-motion testing. Motion in the thoracic spine requires a synchronous movement between the intervertebral and zygapophyseal joints and the rib articulations. T us, the presence of joint dysfunction or degeneration, or structural changes in the spinal curvature, will influence the amount of available range of motion, and the pattern of these coupled motions.[22]

CLINICAL PEARL

It is important to remember that maximum arm elevation requires motion in the upper thoracic segments.

T e inclinometer techniques recommended by the American Medical Association are used to measure thoracic motion objectively.[113]

Flexion. Two inclinometers are used to measure thoracic flexion and both are aligned in the sagittal plane. T e center of the first inclinometer is placed over the T1 spinous process. T e center of the second one is placed over the T12 spinous process. T e patient is asked to slump forward as though trying to place the forehead on the knees, and both inclinometer angles are recorded. T e thoracic flexion angle is calculated by subtracting the T12 from the T1 inclinometer angle. T e patient should be able to flex approximately 20–45 degrees.[67,110] T e clinician observes for any paravertebral fullness during flexion, which might indicate hypertonus from a facilitated segment. T e thoracic spine during flexion should curve forward in a smooth and even manner (Fig. 27-10). T ere should be no evidence of segmental rotation or side bending. To decrease pelvic and hip movements, McKenzie advocates examining thoracic flexion with the patient seated.[114]

Extension. T e clinician places one hand and arm across the upper chest region of the patient and the other hand over the spinous processes of the lower thoracic spine. T e patient is guided into a backward slump (Fig. 27-11). Overpressure is applied by the arm across the front of the patient while avoiding any anterior translation occurring at the lumbar spine.

Clinical guidelines for measurements of thoracic extension recommend that range of motion be defined with reference to the magnitude of the kyphosis measured in standing. However, to date, the relationship between the magnitude of the thoracic kyphosis and the amount of thoracic extension movement has not been reported.[60] T oracic extension may be measured using the same technique and inclinometer positions as described for flexion. T e thoracic extension angle is calculated by subtracting the T12 from the T1 inclinometer angle. T e patient should be able to extend approximately 15–20 degrees.[110] Alternatively, the thoracic extension can be measured using a tape measure. T e distance between two points (the C7 and T12 spinous processes) is measured. A 2.5-cm difference between neutral and extension measurements is considered normal.[112,115] During thoracic extension, the thoracic curve should curve backward or straighten. As with flexion, there should be no evidence of segmental rotation or side bending.

Rotation. T e patient is seated and is asked to turn to each side at the waist. Overpressure is applied through both shoulders (Fig. 27-12). T is motion tests the ability of the ribs and

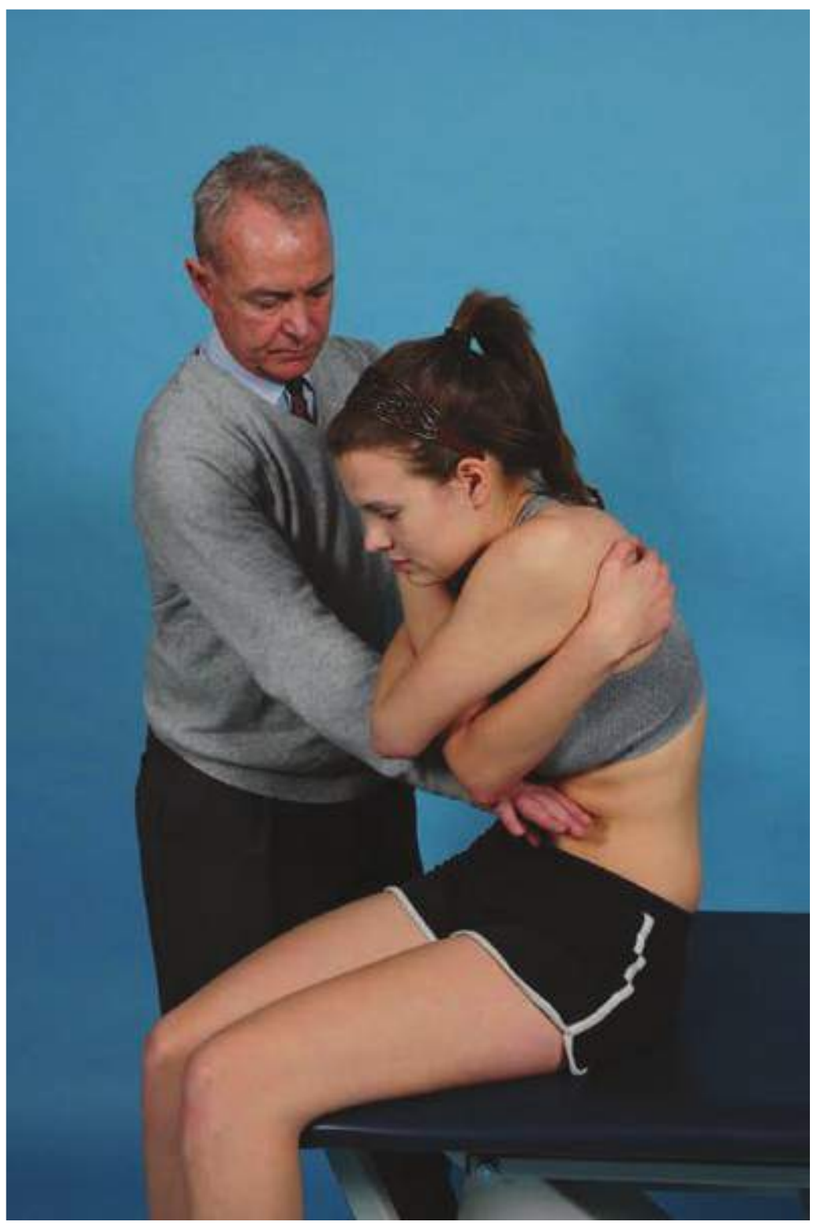

FIGURE 27-10 Thoracic spine flexion.

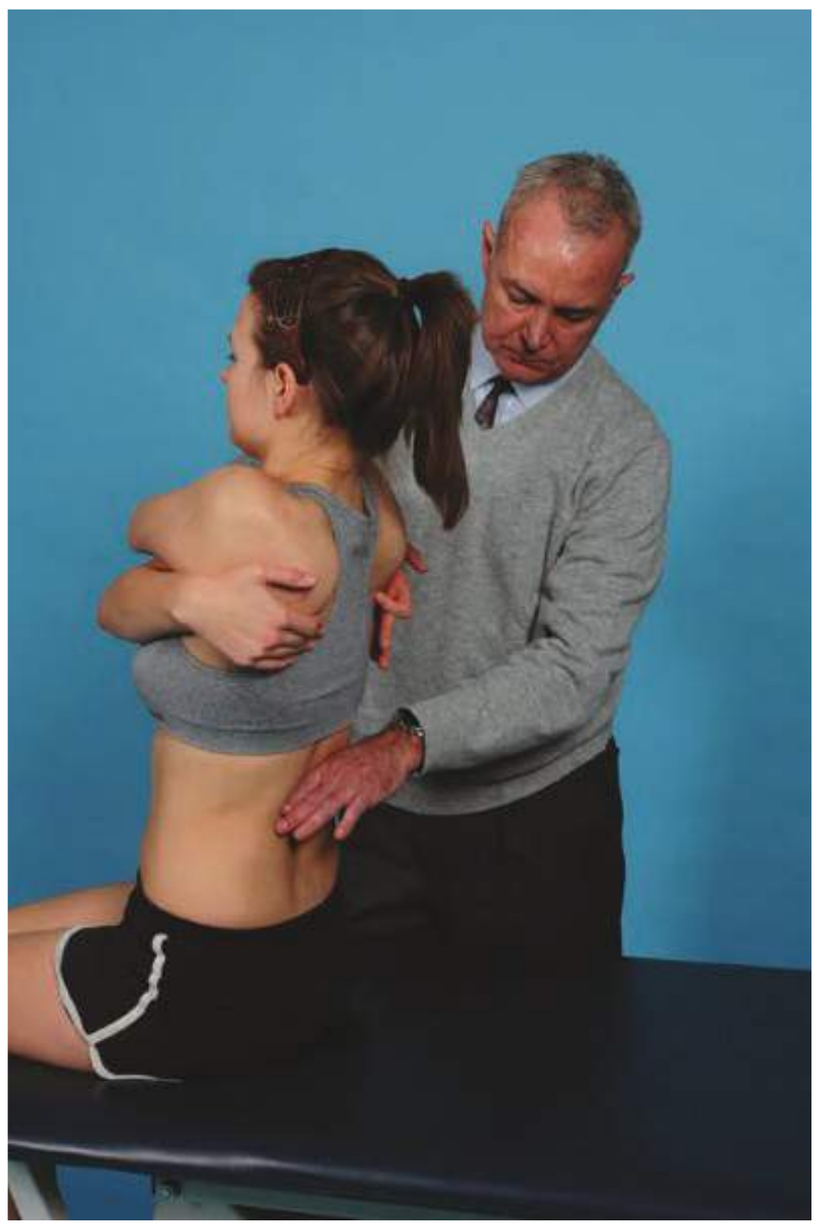

FIGURE 27-11 Thoracic spine extension.

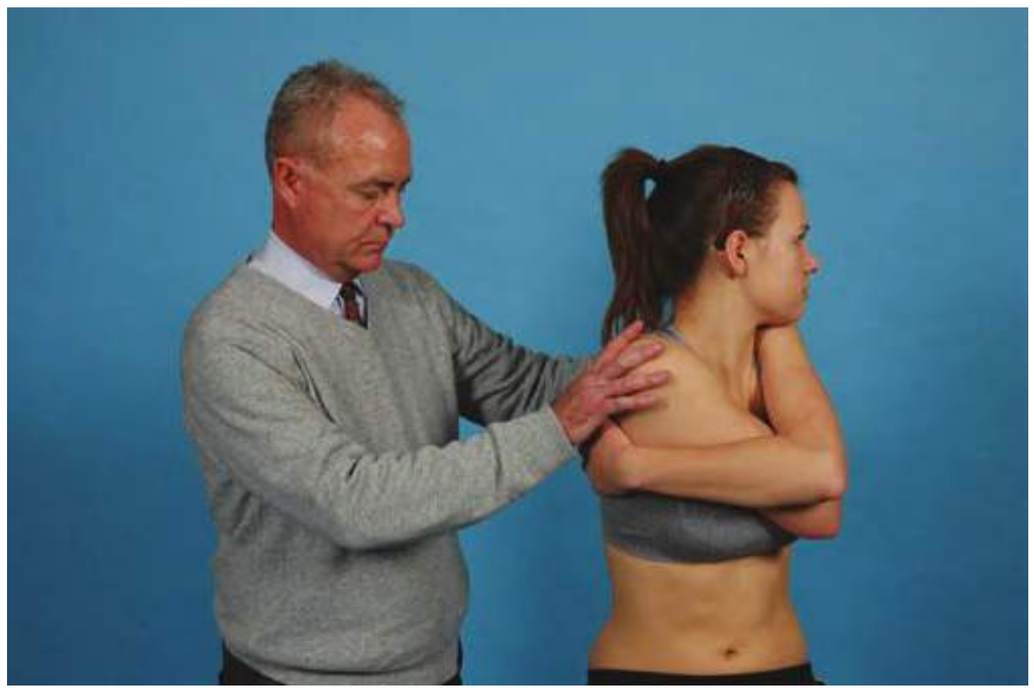

FIGURE 27-12 Thoracic spine rotation.

the superior vertebrae to translate in the direction opposite to the rotation—a motion that is essential if complete rotation and side bending is to occur. A total of 35–50 degrees of rotation is available in the thoracic spine.[22,74] Rotation is a primary movement of the thoracic spine and a key component of functional activities. Active thoracic rotation of 20 degrees or less results in an impairment of function during activities of daily living involving the thoracic spine.[112] Pavelka[116] devised a simple objective clinical method to measure thoracolumbar rotation using a tape measure that can be used to detect asymmetries during rotation. T e tape is placed over the L5 spinous process, wrapped around the trunk, and placed over the jugular notch on the superior aspect of the manubrium. A measurement is taken before and af er full trunk rotation. T e measurements from each side are then compared.

Side Bending. A total of 25–45 degrees of side bending is available in the thoracic spine.[22,74] Using a hand placed against the patient's side, the patient is asked to side bend over the clinician's hand. Overpressure is applied through the contralateral shoulder to avoid compression (Fig. 27-13). Side bending can be measured objectively using a tape measure.[117] Two ink marks are placed on the skin of the lateral trunk. T e upper mark is made at a point where a horizontal line through the xiphisternum crosses the coronal line. T e lower mark is made at the highest point on the iliac crest. T e distance between the two marks is measured in centimeters, with the patient standing erect, and again af er full ipsilateral side bending. T e second measurement is subtracted from the first and the remainder is taken as an index of lateral spinal mobility.

CLINICAL PEARL

A finding of painful and limited side bending away from the painful side, with both rotations free from pain, should always create a suspicion of serious lesions.[91]

Inspiration and Expiration. Using a tape measure, the clinician measures the amount of rib expansion that occurs with a deep breath. T e respiratory excursion is measured at three levels, using a tape measure placed circumferentially around the chest at the level of the axilla, the xiphoid level, and the 10th rib level. Comparisons are made between the

FIGURE 27-13 Thoracic spine side bending.

measurements taken at the position of maximum expiration and the measurement taken at full inspiration. T e normal difference between inspiration and expiration is 3–7.5 cm (1–3 in).[117] Ankylosing spondylitis (see Chapter 5) is a disease that can include ossification of the anterior longitudinal ligament, the thoracic disk, and the thoracic zygapophyseal joints. Findings of ankylosing spondylitis are common in the thoracic region, making chest expansion measurements a requirement in this region. Decreased expansion can highlight the presence of ankylosing spondylitis but may also be the result of diaphragm palsy (C4), intercostal weakness, pulmonary (pleura) problems, old age, a rib fracture, or a chronic lung condition).

T e motions of the ribs are palpated during breathing. If a rib stops moving in relation to the other ribs on the same side during inspiration, it is classified as a depressed rib.[107,118] If a rib stops moving in relation to the other ribs during expiration, it is classified as an elevated rib.[107,118] Because of the interrelationship of all of the ribs, if a depressed rib is implicated, it is usually the most superior depressed rib that causes the most significant dysfunction. In contrast, if an elevated rib is implicated, it is usually the most inferior restricted rib that causes the most significant dysfunction.[107,118]

Resisted Testing

Resistance applied at the point of overpressure can give the clinician an indication of the integrity of the musculotendinous units of this area. Resistance is applied at the end range of thoracic flexion, extension, rotation, and sidebending while the clinician looks for pain, weakness, or painful weakness. Pain that is exacerbated with motion, but not with resisted isometric contraction, suggests a ligamentous lesion.[110]

Respiration

Optimal respiration involves both abdominal and lower rib cage expansion. The most common component lost in patients with thoracic dysfunction is a lateral costal expansion.[119] When lateral/posterior lateral expansion is absent, excessive excursion occurs in the abdomen (making it difficult to attain a functional transversus abdominis contraction) or in the upper chest that (associated with excessive accessory respiratory muscle activity).[119] Three common types of abnormal breathing patterns are recognized.

- Apical. This is characterized by movement in the upper chest during breathing.
- Lateral costal expansion. This is characterized by movement in the lateral lower rib cage during breathing.
- Upper and lower abdominal. This is characterized by an expansion of the abdomen during breathing.

In the ideal scenario, most of the movement on inspiration should occur in the lower lateral rib cage with a concurrent movement of the upper abdomen.[119] Respiration is first assessed through observation over several inspiration/expiration cycles as the clinician looks for where most of the movement occurs during breathing. Following observation, the clinician places both hands on the lateral aspect of the low rib cage and monitors movement during inspiration/expiration, checking for the amount and symmetry of movement between the left and right sides.

Static Postural Testing

A complete postural assessment is described in chapter 6. Thoracic pain of a postural origin is difficult to provoke with active motion and resistive testing. Thus, McKenzie[114] recommends placing the patient in a position for approximately 3 minutes to load the structures sufficiently to provoke postural pain.

Differing Philosophies

The next stage in the examination process depends on the clinician's background. For clinicians who are heavily influenced by the muscle energy techniques of the osteopaths, position testing is used to determine the segment on which to focus. Other clinicians omit the position tests and proceed to the combined motion and passive physiologic tests.

Position Testing: Spinal. The vertebrae may be tested for positional symmetry. If an ERS or FRS is present, passive mobility testing will definitively diagnose the movement impairment. The upper thoracic joints (C7–T4) can be assessed using the cervical techniques described in Chapter 25. The following techniques can be used for the T4–12 levels.

Example: T6–7. The patient is positioned in sitting, with the clinician standing behind. Using one thumb, the clinician palpates the transverse process of the T6 vertebrae. Using the other thumb, the clinician palpates the transverse process of the T7 vertebrae (Fig. 27-14). The joint is tested in the following manner:

- The patient bends forward so that the joint complex is flexed, and an evaluation is made as to the position of the T6 vertebra relative to T7 by noting which transverse process is the most posterior. A posterior left transverse process of T6 relative to T7 is indicative of a left-rotated position of the T6–7 complex in flexion.
- The patient bends backward so that the joint complex is extended, and an evaluation is made as to the position of the T6 vertebra in relation to T7 by noting which transverse process is the most posterior. A posterior left transverse process of T6 relative to T7 is indicative of a left-rotated position of the T6–7 joint complex in extension.

FIGURE 27-14 Position testing for T6–7.

Once a segment has been localized by one of the preceding techniques, the arthrokinematics of the segment can be tested using the following passive mobility tests, which incorporate specific symmetric or asymmetric motions. Care in the interpretation of the passive mobility tests is important, because local tenderness in the thoracic region is common, especially over the spinous processes as a result of the proximity of the posterior (dorsal) rami over the apex of these bony prominences.[23,120]

Combined Motion Testing. As normal function involves complex and combined motions of the thoracic spine, combined motion testing can also be used. The motions tested include forward flexion with side bending, extension with side bending, side bending with flexion, and side bending with extension. The results from these motions are combined with the findings from the history and the single plane motions to categorize the symptomatic responses. This information can guide the clinician when determining which motions to use in the intervention.

Passive Physiologic Mobility Testing. The upper thoracic zygapophyseal joints (C7–T4) can be assessed using the cervical techniques described in Chapter 25. The following techniques can be used for the T4–12 levels.

Flexion of the Zygapophyseal Joints. The patient is seated at the end of the table, with arms together and hands resting on the back of the head. The clinician stands by the side of the patient and reaches around the front of the patient with one arm and hand. The clinician then applies a slight pressure with the sternum against the patient's shoulder so that the patient is gently squeezed. Using the other hand to monitor intersegmental motion between the spinous processes (Fig. 27-15), the clinician flexes the thoracic spine (Fig. 27-15). The quantity and quality of motion are noted and compared with the levels above and below.

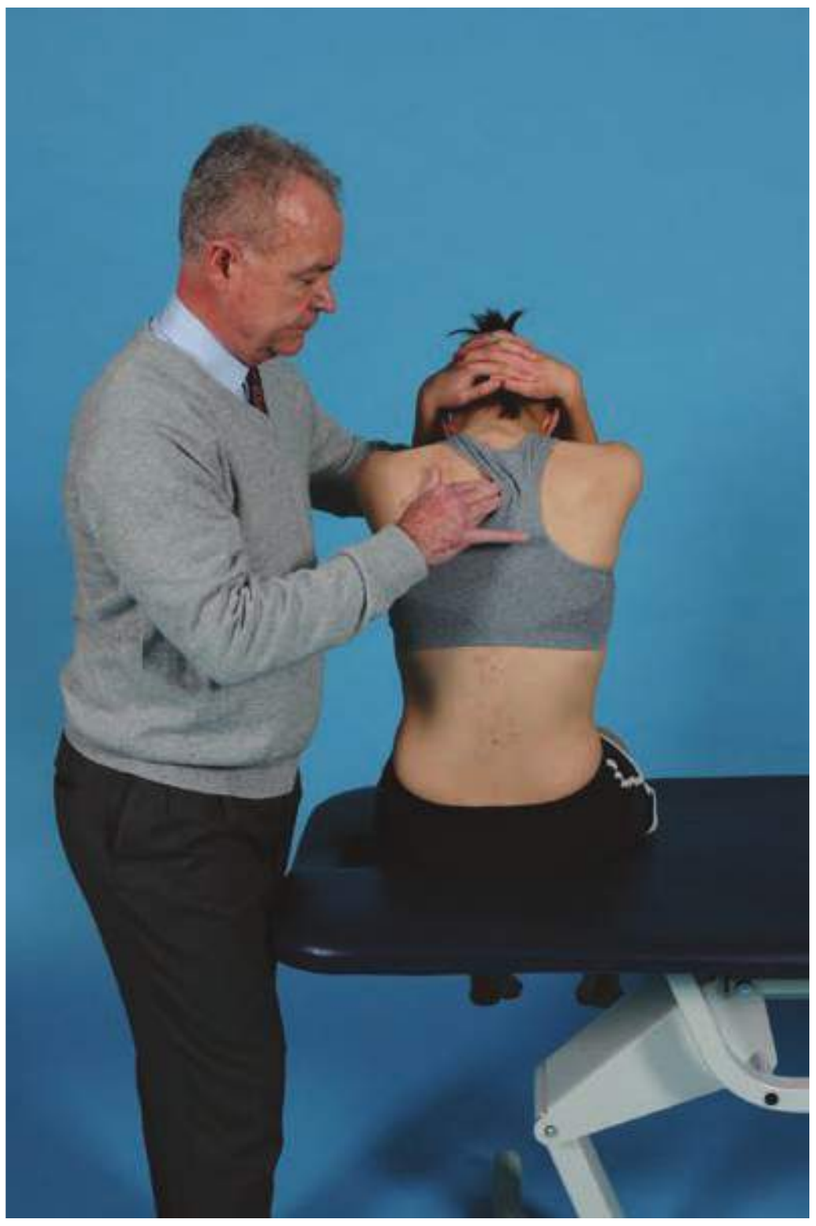

FIGURE 27-15 Passive mobility testing for flexion.

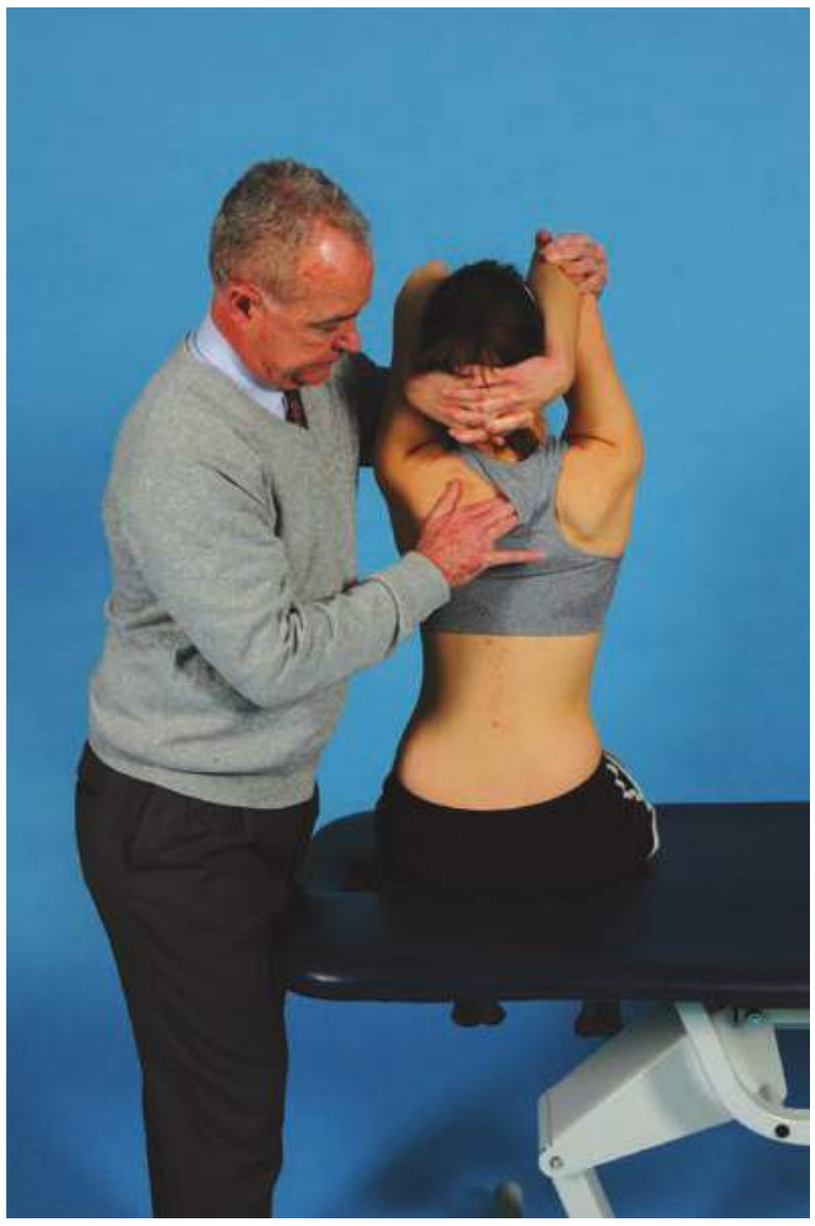

FIGURE 27-16 Passive mobility testing for extension.

Extension of the Zygapophyseal Joints. The patient is seated with the arms together and both hands behind the head. The clinician stands to the side of the patient. While palpating the interspinous spaces or the transverse processes of the level to be tested with one hand, the clinician wraps the other arm around the front of the patient and rests that hand on the patient's contralateral elbow (Fig. 27-16). Crouching slightly, the clinician then places his or her anterior shoulder region close to the lateral aspect of the patient's shoulder. Using the other hand to monitor intersegmental motion between the spinous processes, the clinician extends the thoracic spine (Fig. 27-16). The quantity and quality of motion is noted and compared with the levels above and below.

Combined Motions of the Zygapophyseal Joints. The patient is seated with one hand on top of one of the shoulders and the other hand under the opposite axilla. The clinician stands to the side of the patient. While palpating the interspinous spaces or the transverse processes of each level with one hand, the clinician wraps the other arm around the front of the patient, under the patient's crossed arms, resting his or her hand on the patient's contralateral hand. Crouching slightly, the clinician then places the anterior shoulder region against the lateral aspect of the patient's shoulder. Side bending and rotation of the patient's thoracic spine is then performed away from the clinician (Fig. 27-17), as the clinician lifts with his or her body. The palpating hand palpates the concave side of the curve.

Passive Articular Mobility Testing of the Midthoracic Spine

Under normal circumstances, if the active motions and passive mobility motions of a joint are found to be restricted, the arthrokinematics of the restricted motion(s) are assessed to determine if the hypomobility is articular or extraarticular (myofascial). However, given the number of joints at each segmental level and the proximity of many of them, it is unlikely that passive articular mobility testing in this region will yield any useful information.

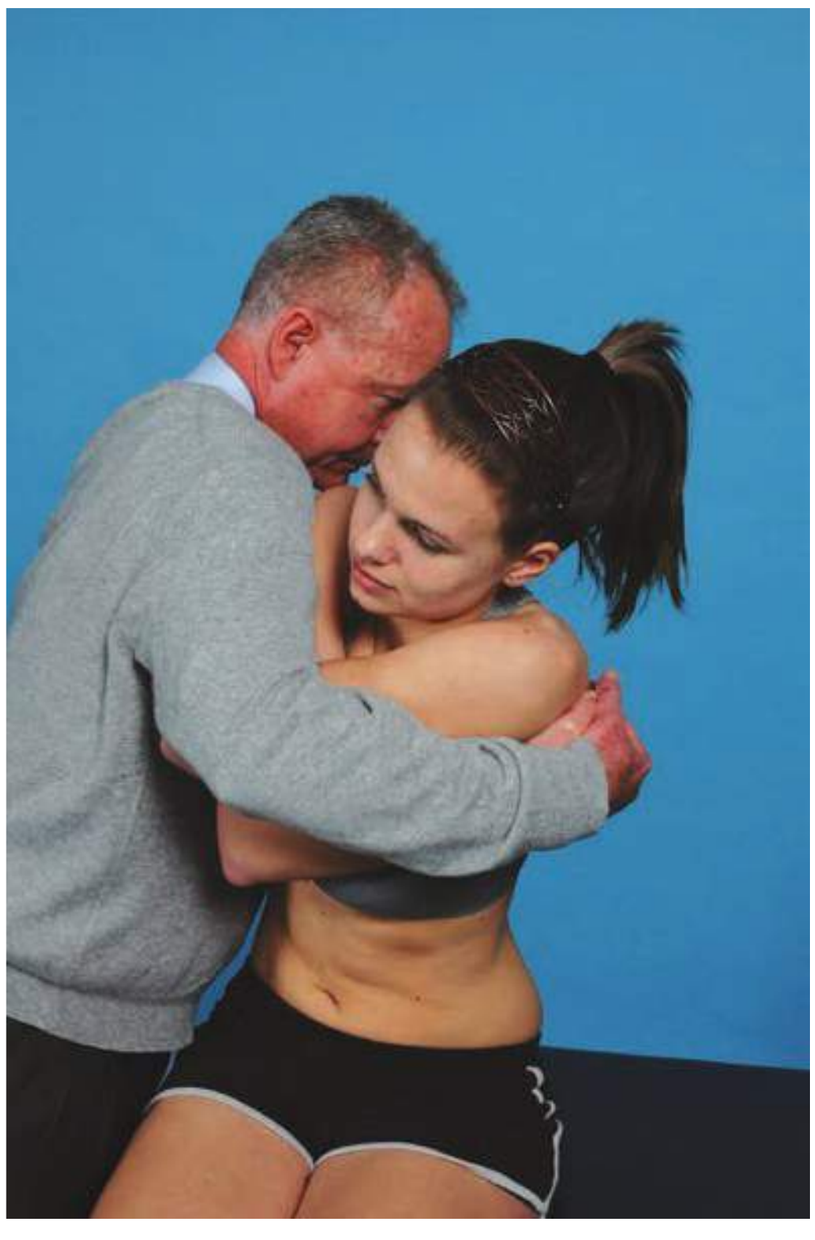

FIGURE 27-17 Passive mobility testing for side bending and rotation away from clinician.

Neurologic Tests

A neurologic deficit is very difficult to detect in the thoracic spine. In this region, one dermatome may be absent with no loss of sensation.[121] Several tests have been devised to help assess the integrity of the neurologic system in this area.

The Slump Test. A neurodynamic mobility test can be used as a general assessment (see Chapter 11).

Sensory Testing. Sensation should be tested over the abdomen. The area just below the xiphoid process is innervated by T8, the umbilicus by T10, and the lower abdominal region, level with the anterior superior iliac spines, by T12.[88] Too much overlap exists above T8 to make sensation testing reliable.

Pathological Reflexes. Because of the proximity and vulnerability of the spinal cord in this region, long tract signs (Babinski, Oppenheim, clonus, and muscle stretch [deep tendon] reflexes) should be routinely assessed.

Lhermitte's Symptom. This is impairment usually is considered to be a lesion to the cervical spinal cord (see Chapter 3), and it is associated with demyelination, prolapsed cervical disk, neck trauma, or subacute combined degeneration of the cord. Because the thoracic cord is immobilized by the denticulate ligaments, flexion will produce only limited stretching of the cord and thus less excursion. Lhermitte's symptom, characterized by an electric shock-like sensation into the spinal cord and limbs during neck flexion, may be present in the thoracic spine with compression of the thoracic cord by metastatic malignant deposits,[122] impairments of the thoracic vertebrae,[123] and thoracic spinal tumors.[124]

Brown–Séquard Syndrome. This syndrome is characterized by ipsilateral flaccid segmental palsy, ipsilateral spastic palsy below the impairment, and ipsilateral anesthesia, loss of proprioception, and loss of appreciation of the vibration of a tuning fork (dysesthesia). Contralateral discrimination of pain sensation and thermoanesthesia may be present and are both noted below the impairment. If a neurologic impairment is suspected, the clinician must first exclude a neoplastic process, infectious process, or fracture, and then consider a disk protrusion. A nondiskal disorder of the thoracic spine could include a neurofibroma; some of the signs to help confirm its presence are that

- the patient reports preferring to sleep sitting up;
- the pain, which slowly increases over a period of months, is felt mainly at night and is uninfluenced by activities;
- the patient reports a band-shaped area of numbness that is related to one dermatome; and
- the patient reports the presence of pins and needles sensations in one or both feet or reports any other sign of cord compression.

Brown–Séquard syndrome symptoms may also occur with an idiopathic spinal cord herniation. This syndrome is caused by damage to the lateral funiculus of the spinal cord. The spinal cord frequently is shifted ventrolaterally and sometimes rotated toward the side of tethering, which might cause unilateral damage of the lateral funiculus. For the diagnosis of spinal cord herniation, magnetic resonance imaging (MRI) and computed tomography (CT) myelography are essential. An MRI myelogram can show acute, angular, anterior (ventral) deviation of the spinal cord in the sagittal plane. CT myelograms can detect anterior (ventral) or ventrolateral shifts of the spinal cord and, sometimes, an extradural cyst in the anterior (ventral) epidural space.

Special Tests

Very few special tests exist for this region, and even fewer have undergone diagnostic accuracy studies to determine reliability, sensitivity, and specificity.

Rib Spring Test. The patient is positioned prone and the clinician stands on one side of the patient. Reaching over the patient, the clinician spreads the length of the thumb and index finger over the right rib in question and applies a posteroanterior force (Fig. 27-18). This is the equivalent of a left rotation of the thoracic spine. The clinician then repeats the posteroanterior force on the rib, except this time, the rotation of the thoracic spine is blocked by the clinician placing the ulnar border of the other hand over a group of left transverse processes. Pain produced with this maneuver implicates the rib because the thoracic spine is stabilized.

Thoracic Spring Test. The patient is positioned as previously. Spring testing in a posteroanterior direction is applied using the thumbs, with the elbows locked over the spinous processes of the thoracic spine (Fig. 27-19). These spring tests are provocative for pain but may also be used for a gross assessment of mobility.

Reflex Hammer Test. The patient is sitting, and the clinician uses a reflex hammer to tap over each spinous process (Fig. 27-20). If tenderness is encountered, especially in a patient with a history of trauma to the area, a fracture must be ruled out.

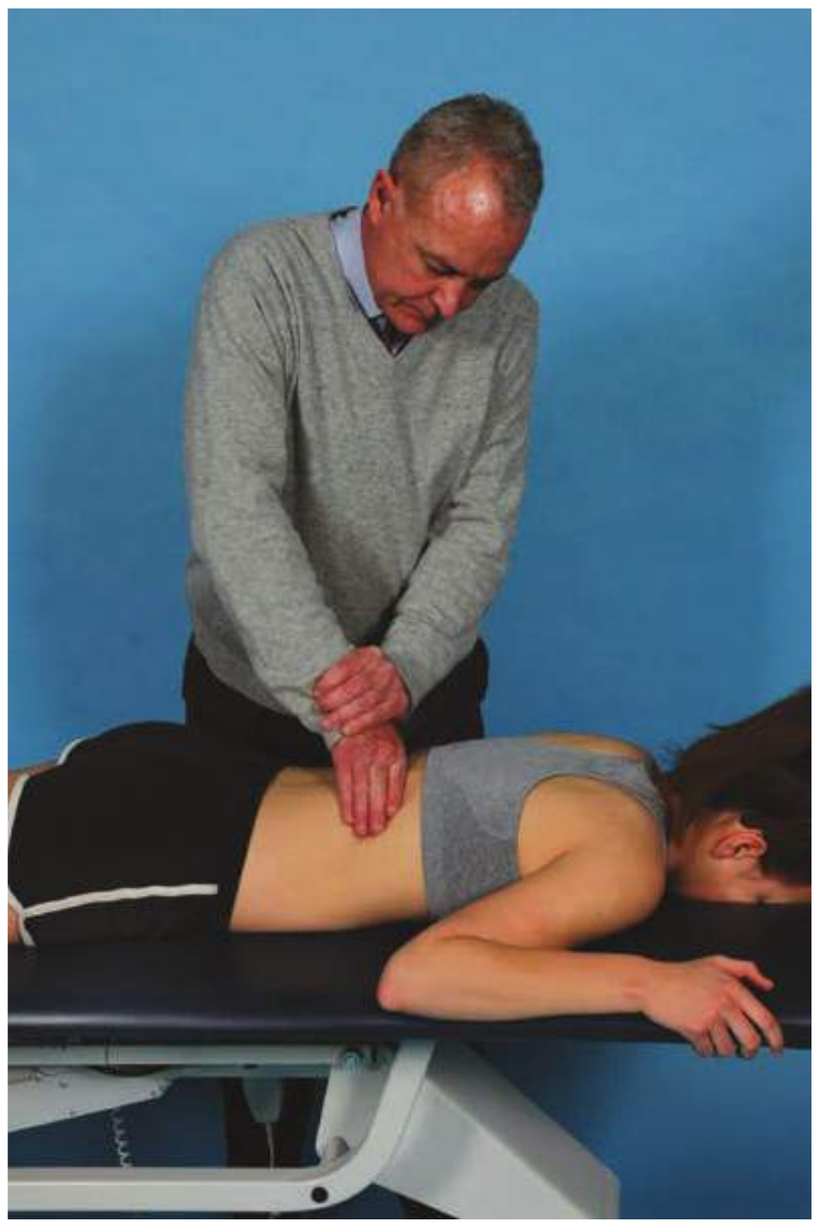

FIGURE 27-18 Rib spring test.

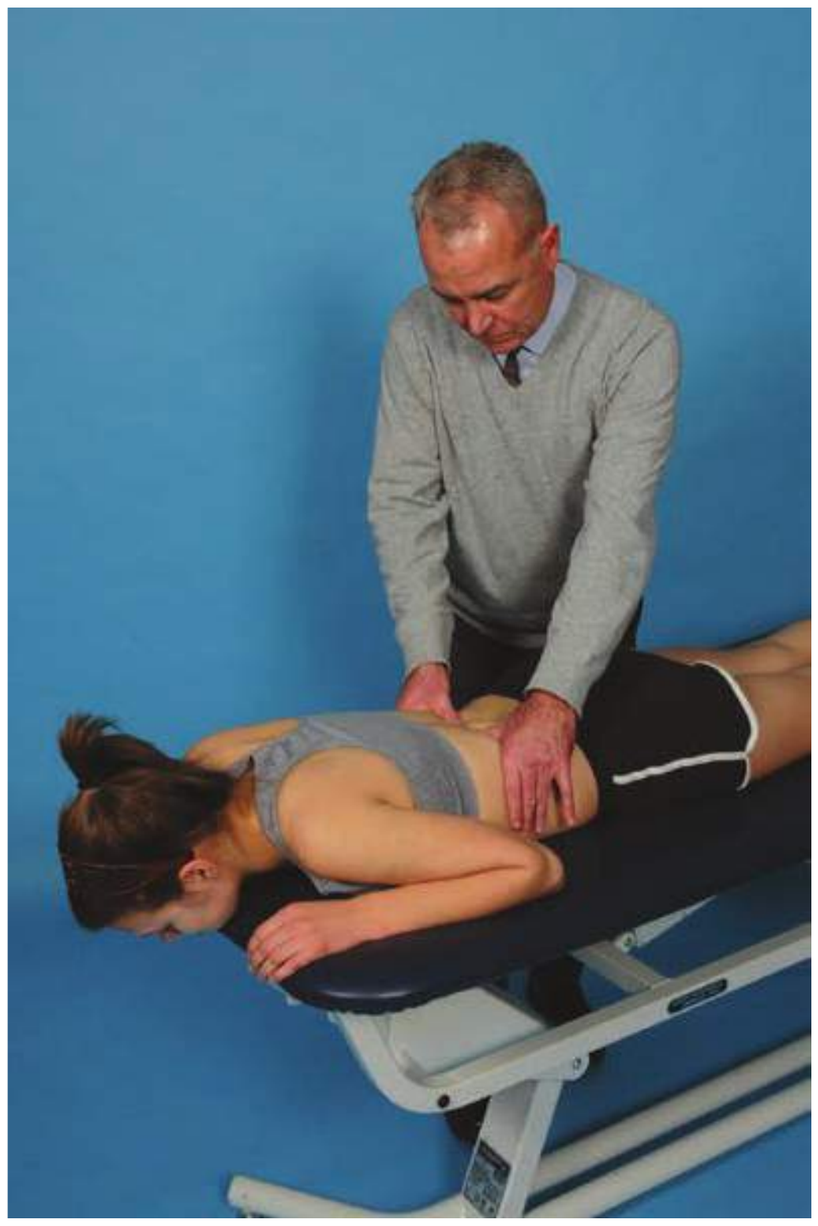

FIGURE 27-19 Thoracic spring test.

Deep Breathing and Flexion. This test can be used for patients who complain of pain with thoracic flexion. The patient is seated with the thoracic spine positioned in neutral. The patient is asked to inhale fully and then to flex the thoracic spine until the pain is felt. At this point, the patient maintains the position of flexion and slowly exhales. If further flexion can be achieved after exhalation, the source of the pain is likely to be the ribs rather than the thoracic spine.[125]

The Sitting Arm Lift Test.[126] The sitting arm lift (SAL) test is based on the principles of the active straight leg raise (see Chapter 29), a validated test of failed load transfer in the pelvic girdle associated with pregnancy-related pelvic girdle pain. The patient is positioned in relaxed sitting with the hand resting on the thighs. The clinician asks the patient to lift one arm (usually the pain-free side is tested first if ipsilaterally symptoms are present), with the arm straight, into elevation and then to lower the arm (Fig. 27-21). Next, the patient is asked to lift the other arm and lower it and the clinician notes whether symptoms are produced, and also observes which arm looks as if it requires more effort to lift, especially from the initiation of movement to the first 70–90 degrees of elevation. Then, the patient is asked "does one arm feel heavier to lift than the other, or different to lift than the other?" If one arm is reported to be heavier or required more effort to lift, the test result is positive for loss of neuromuscular control and indicates a load transfer problem. To determine the affected level or levels, the clinician then palpates the osteokinematic motion of each thoracic ring as the patient performs active elevation through flexion with the heavier arm. A positive test result is indicated when a thoracic ring or rings is/are felt to translate along any axis or rotate in any plane, or any component of the ring (vertebra or rib) translates or rotates along any axis or plane.

The Prone Arm Lift Test.[126] The prone arm lift (PAL) test is a modification of the SAL test as it is performed in a higher load position (prone). The patient is positioned in prone with both arms overhead in approximately 120 degrees of flexion and fully supported on the bed (the head of the bed needs to be dropped down). The clinician instructs the patient to lift one arm and then lower it (Fig. 27-22). The movement is then repeated on the other side. The arm that tests positive for loss of neuromuscular control is the arm that is heavier to lift. As with the SAL test, the same techniques can be used to assess the osteokinematic motions. It is particularly important to assess this ability in patients who require this position functionally (e.g., overhead workers).

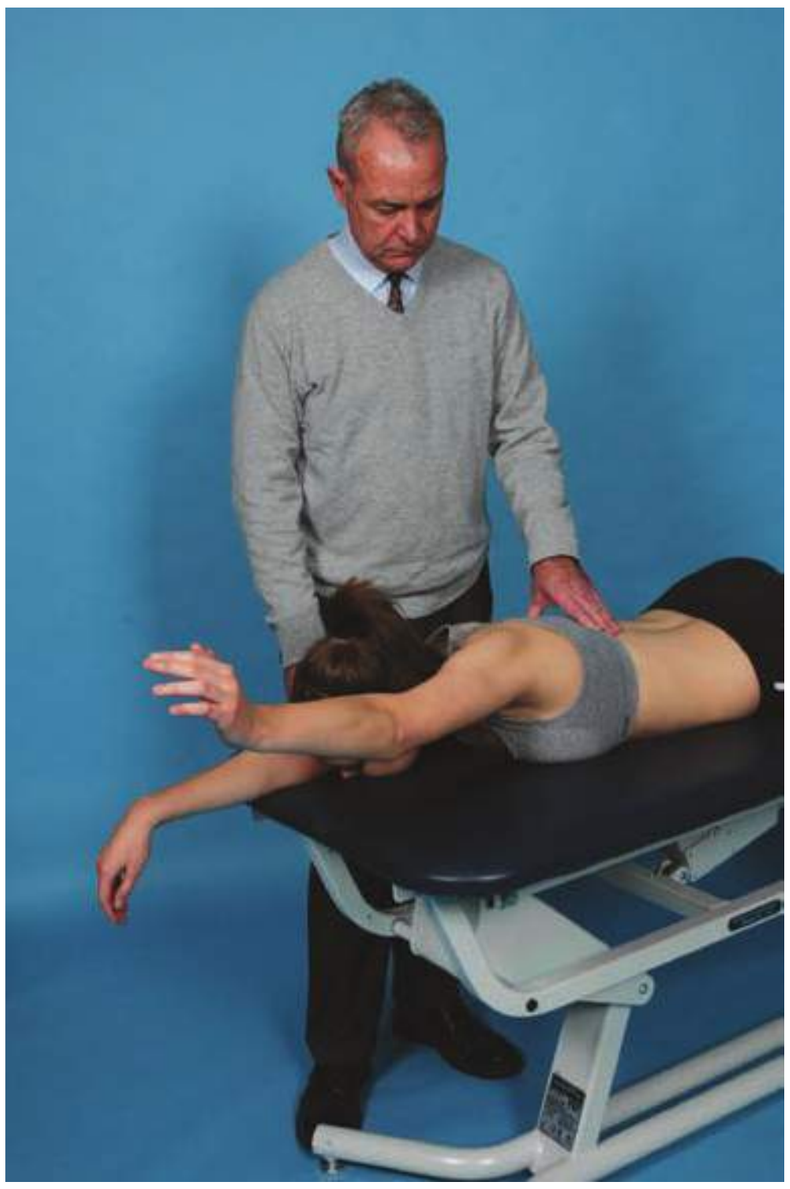

FIGURE 27-22 The prone arm lift (PAL) test.

INTERVENTION STRATEGIES

Interventions for thoracic and rib dysfunctions require a multifaceted and eclectic approach because of the complexity of this area. Once the causes for referral of symptoms have been ruled out, dysfunctions of the thoracic spine and rib cage may be categorized as somatic or biomechanical.

The intervention approach for the upper thoracic spine is similar to that of the cervical spine (see Chapter 25), whereas the approach for the lower thoracic spine is similar to that of the lumbar spine (see Chapter 28). The approach to the midthoracic region is variable and depends on the cause. This region is prone to both postural and biomechanical dysfunctions. The evidence supporting the use of mobilization and high-velocity thrust techniques in the thoracic spine continues to increase.[127–131]

The overall goal of treatment should be to optimize load transfer and the sharing of forces throughout the thorax, the spine, and the entire body, which requires restoration of mobility to restrict areas, restoration of muscle control and the capacity to stabilize poorly controlled areas.[2]

The techniques to increase joint mobility and soft-tissue extensibility are described later, under "Therapeutic Techniques" section.

Acute Phase

In the acute phase of rehabilitation for the thoracic spine, the intervention goals are to

- decrease pain, inflammation, and muscle spasm;
- promote healing of tissues;
- increase pain-free range of vertebral and costal motion;
- regain soft-tissue extensibility;
- regain neuromuscular control;
- initiate postural education;
- promote correct breathing;
- educate the patient about activities to avoid and positions of comfort; and
- allow progression to the functional phase.

Pain relief may be accomplished initially by the use of modalities such as cryotherapy and electrical stimulation, gentle exercises, and occasionally the temporary use of a spinal brace. Thermal modalities—especially ultrasound, with its ability to penetrate deeply—may be used after 48–72 hours. Ultrasound is the most common clinically used deep-heating modality to promote tissue healing.[132–134]

Electrical stimulation can be used in the thoracic region to

- create a muscle contraction through nerve or muscle stimulation. The purpose of this muscle contraction and stimulation is to create a muscle pump to aid in the healing process. Electrical stimulation of muscles for the correction of scoliosis has not been found to be effective in preventing scoliosis progression.[135]
- decrease pain through the stimulation of sensory nerves (TENS);
- provide muscle reeducation and facilitation through both motor and sensory stimulation.

Once the pain and inflammation are controlled, the intervention can progress toward the restoration of full strength, range of motion, and normal posture. Range-of-motion exercises are initiated at the earliest opportunity. These are performed during the early stages in the pain-free ranges. Submaximal isometric exercises are then performed throughout the pain-free ranges. These exercises are progressed as the range of motion and strength increase.

Manual techniques during this phase may include myofascial release, grade I and II joint mobilizations, massage, gentle stretching, and muscle energy techniques.

Functional Phase

The duration of this phase can vary tremendously and depends on several factors.

- Severity of the injury
- Healing capacity of the patient
- How the condition was managed during the acute phase
- The level of patient involvement in the rehabilitation program

The goals of this phase are the following:

- To achieve a significant reduction or to complete resolution of the patient's pain.
- To restore full and pain-free vertebral and costal range of motion. During this phase, the patient learns to initiate and execute functional activities without pain and while dynamically stabilizing the spine in an automatic manner.
- Full integration of the entire upper and lower kinetic chains. The exercises prescribed must challenge and

enhance muscle performance while minimizing loading of the thoracic spine and ribs to reduce the risk of injury exacerbation. Interindividual differences in injury status or training goals may allow for a continuum of required muscle stress and acceptable loading of the spine.[136]

- Complete restoration of respiratory function.
- Restoration of thoracic and upper quadrant strength and neuromuscular control. The stabilization of this region must include postural stabilization retraining of the entire spine, including the stabilization progressions outlined in Chapters 25 and 28, to (1) gain dynamic control of spine forces, (2) eliminate repetitive injury to the motion segments, (3) encourage healing of the injured segment, and (4) possibly alter the degenerative process.[137]

Practice Pattern 4B: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Impaired Posture

Postural Dysfunction

Postural dysfunctions of the thoracic spine are relatively common. Postural pain is not typically reproducible with the typical physical examination, and the diagnosis is based solely on the history of pain following sustained positions or postures. Occasionally, patients with this type of pain may report that their pain is aggravated by stress or fatigue.[138]

Maigne's Thoracic Pain of Lower Cervical Origin. Although the pain from this condition may originate in the thoracic spine, Maigne[111] believes that the vast majority of these cases originate from the lower three cervical segments. The typical patient is female, with complaints of stiffness and tenderness of the shoulder girdle and thoracic muscle groups, particularly the interscapular muscles. The chief complaint is often described as a unilateral and intense pain, which is increased with sustained positions of sitting, and with the lifting and carrying of heavy weights. The pain generally is decreased with rest, although it can sometimes be worse in the morning upon awakening. There may also be accompanying cervical and low-back pain associated with postural habits or standing or sitting positions.

The physical examination usually reveals tenderness at the level of T5–6 (interscapular point), 1–2 cm lateral to the midline. A mild pressure at this point is sufficient to reproduce the patient's pain.

The intervention for this condition involves a therapeutic trial of cervical mobilization.

Abnormal Pelvic Tilting. Good mobility of the pelvis in all directions is important for the thoracic spine. Two postural deviations are associated with pelvic tilting.

1. Posterior pelvic tilting in the sitting position produces an increase in lumbar and thoracic spine flexion and a forward head posture (FHP). This posture is thought to result in a posterior shifting of the thoracic disk, which in turn places stress on the posterior longitudinal ligament and the dura mater. This stress can produce both local and nonsegmental referrals of pain. This condition can be treated by having the patient sit on a wedge that tilts the pelvis anteriorly.
2. Anterior pelvic tilting in the standing position causes the trunk to lean backward and results in overstretching of the rectus abdominis and a pulling forward of the shoulders, shortening of the posterior neck muscles, and increased extension of the atlantooccipital joint. This condition can be treated by having the patient perform posterior pelvic tilts while standing, or by standing with one foot in front of the other.

Precordial Catch Syndrome. This is a benign self-limiting condition occurring mainly in adolescents and young adults.[139,140] It is characterized by sharp, stabbing pain in the precordial and left parasternal region that does not radiate. This pain usually lasts a few seconds and may occur at rest or with mild-to-moderate exercise.[139] When occurring at rest, it is often associated with being seated in a slouched position and may be relieved by stretching into a more upright position.[141] It affects males and females equally but is uncommon after the age of 35 years.[140] The etiology of this condition is unknown, but it may originate from the pleura.[140] After excluding other causes, management consists of explanation, reassurance, postural education, and exercises to correct any muscle imbalances.

CLINICAL PEARL

Patients with any form of postural dysfunction often benefit from the movement therapies of the Alexander technique, Feldenkrais method, Trager psychophysical integration, Pilates, and tai chi chuan[142–148] (see Chapter 10).

Practice Pattern 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Ligament or Other Connective Tissue Disorders

Thoracic Disk Pathology

Herniated disks have been found at every level of the thoracic spine, although they are more common in the lower thoracic spine.[11,149]

At the cervical and lumbar levels, the thoracic spinal nerves emerge from the cord as a large anterior (ventral), and a smaller posterior (dorsal) ramus, which unite to form a short spinal nerve root. There are no plexuses in this area and the spinal nerves form the intercostal nerves.[8] The intraspinal course of the upper thoracic nerve root is almost horizontal (as in the cervical spine). Therefore, the nerve can only be compressed by its corresponding disk. More inferiorly in the spine, though, the course of the nerve root becomes more oblique, and the lowest thoracic nerve roots can be compressed by disk impairments of two consecutive levels (T12 root by 11th or 12th disk).[8]

The major etiological factor in most cases of thoracic disk herniation appears to be degenerative changes in the disk.[150] McKenzie[114] argues that the derangement syndrome can be divided into posterior and anterior disk derangements because of the distinct clinical presentations. The McKenzie

classification system is outlined in Chapter 22. Anterior derangement is rare in the thoracic spine. The following derangement patterns are seen in the thoracic spine[114]:

- Derangement 1. This type of derangement typically produces central or symmetric pain between T1 and T12. These derangements are rapidly reversible.
- Derangement 2. This type of derangement, which is rare and the result of acute trauma or serious pathology, produces an acute kyphosis.
- Derangement 3. This type of derangement typically produces unilateral or asymmetric pain across the thoracic region, with or without radiation around the chest wall. These derangements are rapidly reversible.

CLINICAL PEARL

The clinical manifestations of thoracic disk herniation are extremely variable and vague. This often results in long delays between presentation and diagnosis.

Midline back pain and compressive myelopathy symptoms progressing over months or years are the predominant clinical features of a thoracic disk herniation.[21] One study[151] found that 70% of patients had signs of spinal cord compression, but that isolated root pain occurred in only 9% of patients. Unusual features of thoracic disk herniation include Lhermitte's symptom precipitated by rotation of the thoracic spine,[152] neurogenic claudication with positional dependent weakness,[153] and flaccid paraplegia.[154]

Some thoracic disk herniations are asymptomatic. The incidence of asymptomatic thoracic disk protrusions is approximately 37%, reinforcing the view that clinicians should interpret thoracic MRI findings with caution.[11,149]

T1 and T2 Levels. Disk herniations at these levels are extremely rare.[155] This is rarity may be due to the protection afforded by the presence of the first and second ribs. Compression of the nerve at the T1 and at T2 segmental levels may result in numbness, tingling and weakness of the hand, and pain in arm and medial forearm.[155] T1 radiculopathy may also be associated with a Horner's syndrome.[155] The patient may also have reduced biceps and triceps reflexes.[155]

T2 and T3 Levels. A disk herniation at these levels is the rarest type.[156] Symptoms produced by this herniation include pain referred toward the clavicle, to the scapular spine, and down the inner side of the upper arm.[156]

T3–8 Levels. Compression of the nerves at these lower levels may result in symptoms that are experienced at the side, or front of the trunk.[91] Compression of the dura in the thoracic spine results in unilaterally referred pain, which is extrasegmental. A T6-level compression of the dura can cause pain up to the base of the neck and down to the waist whereas a dural compression at T12 can refer pain up to T6 and down to the sacrum.[91]

T9–11 Levels. Lower thoracic disk herniations have been associated with pain radiating to the buttock in some cases, confusing the diagnosis with that of a lumbosacral root compression.[157] How a herniated disk at a low thoracic level could appear to be a lumbosacral radiculopathy may be best explained by the anatomic arrangement of the spinal cord and vertebral bodies. In adults, the conus medullaris ends between the 12th thoracic and 3rd lumbar vertebrae, and the lumbar enlargement of the spinal cord is usually located at the lower thoracic level. Therefore, a lower thoracic disk herniation could compress the lumbosacral spinal nerves after their exit from the lumbar enlargement of the spinal cord and thus produce symptoms of compressive lumbosacral radiculopathy; thus, a herniation into an already tight canal may produce bilateral symptoms and sphincter disturbance, as in patients with a conus medullaris impairment.[158]

A retrospective study by Brown et al.[159] found that 77% of the 40 patients with symptomatic thoracic disk herniations, who were treated nonsurgically, were able to return to their previous level of activity.

Thoracic disk herniations requiring surgical management are uncommon and account for less than 2% of all operations performed on herniated IVDs.[160]

Electrodiagnosis of Thoracic Disk Lesions. Electrodiagnostic studies are important in identifying physiologic abnormalities of the nerve root in the cervical, thoracic, and lumbar spine, and they have been shown to be a useful diagnostic test in the diagnosis of radiculopathy,[161] correlating well with findings on myelography and surgery.[162,163]

There are two parts to the electromyogram: nerve conduction studies and needle electrode examination. The nerve conduction studies are performed by placing surface electrodes over a muscle belly or sensory area and stimulating the nerve, supplying either the muscle or the sensory area from fixed points along the nerve. From this, the amplitude, distal latency, and conduction velocity can be measured. The amplitude reflects the number of intact axons, whereas the distal latency and conduction velocity are more of a reflection of the degree of myelination.[164–166]

The timing of the examination is important, as positive sharp waves and fibrillation potentials will first occur 18–21 days after the onset of a radiculopathy.[165,167] It is, therefore, best to delay this study until 3 weeks after the injury, so that it can be as precise a study as possible. The primary use of electromyography is to diagnose nerve root impairment when the diagnosis is uncertain or to distinguish a radiculopathy from other impairments that are unclear on physical examination.[165] Electrodiagnostic abnormalities can persist after clinical recovery for months to years and in some may persist indefinitely.[168,169]

Traction: Mechanical or Manual for Thoracic Disk Lesions. Manual or mechanical traction has long been a preferred intervention throughout the spine with the intent of improving range of motion, and to treat both zygapophyseal joint impairments as well as disk herniation.[170–175] The efficacy of traction has not been scientifically proved in a randomized controlled trial, but it is commonly used and thought to be of benefit in reducing radicular pain.[176]

For traction to be effective, the imparted force must be sufficient to overcome soft-tissue resistance prior to the relaxation of the involved musculature.

Traction can be applied continuously, or intermittently, and with the patient positioned in sitting or lying.[177] Intermittent traction produces twice as much separation as sustained.[178]

T e duration of traction recommended varies from 2 minutes to 24 hours.[179]

Performed manually, traction can be very time consuming and, in the lumbar and thoracic spines, requires a good deal of strength—approximately 1–2 times a patient's body weight is needed to develop significant distraction of the vertebral bodies. However, a greater degree of specificity can be obtained using manual traction, especially if it is performed using spinal locking techniques to localize the distraction to a specific level. Pain relief, or a centralization of symptoms, with manual traction may also be an indication for the use of mechanical traction.

Vertebral axial decompression, a newer method to cause a distraction, probably represents a higher-tech version of traction, although there is no evidence in the current peer-reviewed literature to support this type of intervention.

Outcome studies of traction have demonstrated varying results.[170,175] From clinical experience, it would appear that traction yields better results if at least one of the spinal motions is full and pain free. However, a one-session trial of short duration is worthwhile, even if all of the motions are restricted.

Spinal traction is contraindicated in the following conditions:

- acute lumbago;
- instability;
- respiratory or cardiac insufficiency;
- respiratory irritation;
- painful reactions;
- a large extrusion;
- medial disk herniation; and
- altered mental state; this includes the inability of the patient to relax.

Electrotherapeutic and Physical Modalities of Thoracic Disk Lesions. Modalities such as electrical stimulation also have been found helpful in uncontrolled studies.[180] T ey appear to be helpful in reducing the associated muscle pain and spasm but should be limited to the initial pain-control phase of the intervention.

Once there is control of pain and inflammation, the patient's intervention should be progressed to restore full range of motion and flexibility of the spine, trunk, and extremity muscles.

Zygapophyseal Joint Dysfunction

Apart from the upper and lower segments of this region, little is known about the extent or patterns of thoracic zygapophyseal joint degeneration. However, these joints have been found to be potential sources of local and referred pain.[181]

T e pathomechanics describing mechanical dysfunction in this region are largely based on expert opinion and the principles of anatomy and biomechanics. Given the controversy surrounding the nature of coupled motions in the thoracic spine, and the number of structures involved in executing motion at these levels, the clinician is advised to diagnose dysfunction in this region based on restrictions of motion, rather than on specific structures.

Restriction of motion can have many causes in this region, including zygapophyseal joint hypomobility, sof -tissue contracture, and costovertebral–costotransverse joint hypomobility. Differentiation of these structures, to find the specific cause of dysfunction, requires a great deal of expertise.

For the sake of simplicity, and because the spinous and transverse processes are more easily palpated in this region, the osteopathic approach to diagnosing a positional dysfunction using position testing is recommended.

As elsewhere in the spine, dysfunctions can be either symmetric or asymmetric. Symmetric impairments are more common in the thoracic region than in the lumbar, particularly in the upper and cervicothoracic spine as a result of fixed postural impairments. T ese, of course, will not be apparent on position testing and must be sought af er when the position tests are negative. If no asymmetry is found on position testing, then the segment of interest should be separately passively flexed, extended, and rotated in all directions.

Layer palpation is used to determine which lesion is present. T e position of the superior vertebra and the posteroanterior relationship of the transverse processes to the coronal body plane is noted and compared with the level above and below, in thoracic flexion and then extension (see "Position Testing: Spinal" section earlier).

Rib Dysfunction

T e costovertebral joint may be involved in inflammatory or degenerative joint disease. Complaints of symptoms in these joints are common in conditions such as ankylosing spondylitis as a result of synovitis. T e clinical features of severe arthropathy of the costovertebral joint include pain with deep breathing, trunk rotation, sneezing, or coughing. CT scans are helpful in confirming the diagnosis. Inflammation of the costovertebral joint commonly causes localized pain about 3–4 cm from the midline, where the rib articulates with the transverse process and the vertebral body.[82]

According to the osteopaths, rib dysfunctions are described as structural, torsional, or respiratory.[106,182,183]

- Structural. Structural rib dysfunctions are true joint subluxations that occur secondary to trauma. T ese dysfunctions are extremely painful and significantly reduce motion of the ribs during inspiration and expiration. T e most important landmarks for structural rib dysfunctions are the rib angle and the anterior rib. Ribs can sublux anteriorly or posteriorly (see Table 27-4).
- Torsional. As their name suggests, these rib dysfunctions are twisting injuries, in which the rib is held in a position of internal or external rotation. T ese dysfunctions affect the thoracic spine motions as well as the motions of respiration (see Table 27-4).
- Respiratory. Respiratory rib dysfunctions usually are related to poor posture and result in a restriction of either inspiration or expiration.

T e first rib can sublux anteriorly, posteriorly, or, more commonly, superiorly. If the motion is perceived as abnormal, passive movement testing should be performed. T e arthrokinematic is tested with the patient seated and the clinician

standing behind. Using the medial aspect of the MCP joint of the index finger, the clinician applies an anterior–inferior–medial glide of the rib to assess the inspiration glide, while a posterior–superior–lateral glide is applied to assess the expiration glide. The end-feel is assessed. If it is abrupt and hard (pathomechanical) in both glide directions as compared with the same rib on the other side, then the problem is a subluxation. If it is stiff (hard capsular) in both directions as compared with the same rib on the other side, then a pericapsular restriction is present. If both glides are normal, then the problem is likely to be myofascial.

- Unilateral restriction of anterior rotation of the first rib. This dysfunction is seen when the scalene muscles are hypertonic or adaptively shortened and hold the anterior aspect of the first rib superiorly or when the superior glide of the first rib is restricted at the costotransverse joint. This dysfunction will restrict unilateral elevation of the arm (both arms may be involved). If the dysfunction is intraarticular, rotation and side bending of the head/neck will be limited to the side of the restricted rib (this motion requires a superior glide of the rib at the costotransverse joint). Full expiration will also reveal asymmetry of rib motion. If the restriction is intraarticular, the superior glide of the first rib at the costotransverse joint will be restricted. The presence or absence of pain depends upon the stage of the pathology (substrate, fibroblastic, and maturation) and the irritability of the surrounding tissue. The grade of the mobilization technique is directed by these factors.
- Unilateral restriction of posterior rotation of the first rib. This dysfunction, also known as an expiratory or anterior sagittal lesion, is seen when the posterior aspect of the first rib is held superiorly or when the inferior glide of the first rib is restricted at the costotransverse joint. This dysfunction will restrict unilateral elevation of the arm on either side, rotation and side bending of the head/neck to the opposite side of the restricted rib, and full inspiration. If the restriction is intraarticular, the inferior glide of the first rib at the costotransverse joint will be restricted. The presence or absence of pain depends on the stage of the pathology (substrate, fibroblastic, and maturation) and the irritability of the surrounding tissue. The grade of the mobilization technique is directed by these factors.

The intervention for costovertebral dysfunctions involves mobilization and manipulation techniques or local anesthetic injections, or both.

Practice Pattern 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Localized Inflammation

Tietze Syndrome

Tietze syndrome is a local inflammation of the costosternal cartilage, which most commonly affects the second and third costochondral junctions.[28,153] Tietze syndrome may also affect any of the cartilaginous articulations of the chest wall, including the sternoclavicular joints.[184]

The clinical findings for this condition include a history of a gradual or sudden onset of pain in the involved region, which is increased with deep inspiration, coughing, or sneezing. Upon physical examination, there is often a localized swelling of the costosternal cartilage.

This is a self-limiting condition, which can last from weeks to years. The intervention can involve local injections of corticosteroid and specific joint mobilizations to the costovertebral articulations.

Muscle Strains

Muscle strains, which are common in this region, are characterized by localized pain and tenderness, which is exacerbated with isometric testing or passive stretching of the muscle. Rather than attempt to isolate muscles in this region, the clinician can determine the directions that alleviate the symptoms and those that do not. A gradual strengthening and gentle, passive stretching program into the painless directions is initially performed, before progressing as tolerated into the painful directions.

Intercostal Muscles. Injuries to intercostal muscles are mainly caused by direct trauma or after unaccustomed or excessive muscular activity (e.g., lifting a heavy object or persistent coughing).[185] On occasion, the onset of pain or symptoms may be of gradual onset with no obvious inciting event.[186] Intercostal muscle injuries are more likely in activities in which upper body use is extreme, such as regular use of a pickaxe.[186]

The classic presentation is pain between the ribs that is worse on movement, deep inspiration, or coughing, and tender to palpation.

The intervention for intercostals muscle strains includes antiinflammatory medications, the avoidance of exacerbating activities, and the treatment of any underlying pathology where appropriate.

Contusions

The severity of soft-tissue injury to the chest wall is dependent on the mechanism of injury and the degree of protection between the traumatic force and the chest wall.[53] Chest injury is commonly produced by the restraining influence of the diagonal component of a seat belt. Seat belt injuries occur predominantly on the side of the belt and hence occur on different sides in drivers and passengers.[53] These take the form of abrasions, ecchymoses, and friction burns, producing an imprint of the belt.[53]

Trauma to the female breast can be produced by a combination of compression and shearing stress produced by a seat belt and subcutaneous rupture of breast tissue can occur.[187] The presence of a persistent breast mass after trauma must always be taken seriously, as trauma may draw attention to an unsuspected carcinoma.[53]

Chest trauma can result in disruption of a subcutaneously placed pacemaker generator or leads, long-term indwelling central venous catheter, or subcutaneous portions of arterial bypass grafts.[53]

Severe skeletal trauma to the chest wall can be associated with large chest wall hematomas or collections of air within the chest wall, which can communicate with the intrathoracic space.[53]

The conservative intervention for thoracic cage contusions depends on the severity of the injury and the tissues involved. Typically, the initial intervention for soft-tissue injury is cryotherapy with rest. Gentle pain-free active range-of-motion exercises are introduced as tolerated. Once the acute stage is over, thermal modalities are used, and the range-of-motion exercises progressed to strengthening exercises in all planes.

Practice Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Fractures

Thoracic Vertebral Fractures

Fractures of the thoracic spine account for 25–30% of all spine fractures.[188] These fractures are most often a result of hyperflexion or axial loading injuries[189] and less commonly attributable to rotational stresses, side bending, horizontal shear, and hyperextension. The most common fractures seen in the thoracic spine are anterior wedge compression fractures and burst fractures[190] (see Chapter 5). Most thoracic spine fractures secondary to osteoporosis occur between the 9th and 11th vertebral bodies. Multiple fractures are found in 10% of all patients with a spine fracture, and, therefore, evaluation of the entire spine is necessary, because up to 80% of these additional fractures are noncontiguous.[191] Only 12% of patients with fracture–dislocations of the thoracic spine are neurologically intact, and 62% of patients with thoracic spine fracture–dislocations have complete neurologic deficits.[53]

Rib Fractures

Fractured ribs can lacerate the pleura, lung, or abdominal organs. Fractures of the upper ribs, clavicle, and upper sternum can signal brachial plexus or vascular injury. Isolated fractures of the ribs, clavicle, or scapula seldom represent significant injuries in and of themselves, but they do reflect the magnitude of force imparted, particularly in older patients with noncompliant chest walls.[192] Fractured rib ends can lacerate the pleura or lung, resulting in hemothorax or pneumothorax.[53] There is a much greater incidence of rib fractures in older patients, whose ribs are relatively inelastic, compared with the incidence of rib fractures in children, whose ribs are more pliable and resilient.[53] For this reason, a posttraumatic pneumothorax in older patients is almost always associated with one or more rib fractures, whereas children can sustain a pneumothorax or major internal thoracic injury after trauma without an associated rib fracture.

Fractures of the first three ribs, in particular, indicate significant energy transfer, because they are well protected by the shoulder girdles and associated musculature.[53] Fractures to the upper ribs, clavicle, and upper sternum are accompanied by brachial plexus or vascular injury in 3–15% of patients.[193] Fractures of the 10th, 11th, or 12th ribs are associated with injury to the liver, kidneys, or spleen and should prompt confirmation of organ injury with CT.[53] Double fractures of three or more adjacent ribs or contiguous combined rib and sternal or costochondral fractures, or single fractures of four or more contiguous ribs, can produce a focal area of chest wall instability. Paradoxical movement of a "flail" segment during the respiratory cycle can impair respiratory mechanics, promote atelectasis, and impair pulmonary drainage.

The common findings for a rib fracture are described in Chapter 5. A key factor in the intervention of rib fractures is believed to be adequate pain control to allow early aggressive respiratory care and, hence, prevent the development of pulmonary complications.

Early intervention includes assistance with coughing, intracostal nerve blocks, and muscle relaxants. Adhesive strapping or taping should be avoided because it can inhibit deep inspiration and may contribute to atelectasis.[194] Simple rib fractures become stable in 1–2 weeks, with firm healing by callus in approximately 6 weeks.[194]

Scheuermann's Disease

Scheuermann's disease, which is found in approximately 10% of the population and in males and females equally, is typically seen in pubescent athletes.[195]

The disease involves a defect to the ring apophysis of the vertebral body and anterior wedging of the affected vertebrae, as a result of a flexion overload of the anterior vertebral body.[196] The end plate can crack, thus making it possible for disk material to bulge into the vertebral body (Schmorl's node). According to McKenzie,[114] the extension dysfunction develops in patients with Scheuermann's disease as a result of adaptive shortening from poor postural habits, or from derangement or trauma and the healing process.

Clinical findings include evidence of a thoracic kyphosis and pain with thoracic extension and rotation.

The intervention depends on the severity but typically involves postural education, a modification of the aggravating activity, exercise (seated rotation and extension in lying exercises), or bracing. The exercise program involves the stretching of the pectoralis major and minor muscles, and muscle-strengthening exercises for the thoracic spine extensors and the scapular adductors.[36]

Scapular Fractures

Fractures of the scapula are relatively rare due to the thick muscles lying both superficial and deep to the scapula and the energy-absorbing ability of the scapula to move on the chest wall.[197] Because a large amount of force is required to fracture a scapula; these fractures are often associated with other major injuries. For example, the incidence of pneumothorax in patients with fracture of a scapula is over 50%.[198] Associated injuries that are directly related to the fractured scapula include injuries of the suprascapular nerve, axillary nerve, axillary artery, and subclavian artery.[52] The body of the scapula is the most frequent site of fracture followed by the neck and glenoid.[199] The spine, coracoid, and acromion are less frequently fractured.[199] Scapular fractures may not be recognized on the initial chest radiograph as they are frequently radiographically obscure and are commonly associated with multiple other regional injuries, such as clavicular and rib fractures, subcutaneous air, pneumothorax, and pulmonary contusion.[53]

Sternal Fractures. The tremendous force necessary to cause a fracture of the sternum has led to the belief that the presence of a sternal fracture is a harbinger of severe associated

injuries. The association of seat belt wearing with sternal fractures is well known.[200] A proportional increase in the incidence of 100% in drivers and 150% in front-seat passengers has been noted since the enactment of seat belt legislation.[201] Sternal fractures, as such, do not generally cause problems either in healing or by direct damage to adjacent structures. Dislocation of the sternoclavicular joint, however, with posterior displacement of the inner end of the clavicle may cause compression of the trachea and the adjacent vessels, with significant clinical consequences.[202]

Integration of Practice Patterns 4B and 4F: Impaired Joint Mobility, Motor Function, Muscle Performance, Range of Motion Secondary to Impaired Posture, Systemic Dysfunction (Referred Pain Syndromes), Spinal Disorders, and Myofascial Pain Dysfunction

Referred Pain

Referred pain to this area is extremely common. Referred pain is characterized by a poorly localized pain that is nontender to palpation and does not change with movements or alterations of posture (see Table 27-6).

T4 Syndrome

The name of this syndrome is a bit of a misnomer because the syndrome can additionally affect any of the T2–7 levels although it always includes the T4 segment. The T4 syndrome has an unknown etiology, although it is believed to result from a sympathetic reaction to a hypomobile segment because the symptoms appear to resolve in response to manual therapy techniques to the thoracic segments.[203–205] In the thorax, the sympathetic trunks lie on or just lateral to the costovertebral joints. These trunks may undergo mechanical deformation with abnormal posture (forward head, accentuated thoracic kyphosis, and protracted shoulder girdle), trauma, or pulling and reaching activities, producing pain and sympathetic epiphenomena.[206]

Neurovascular symptoms are not a feature of this syndrome though a differential diagnosis should consider such conditions.[203] The upper extremity symptoms are glovelike in distribution and are not segmentally related.[204] Nocturnal symptoms are common, usually occurring in the side lying or supine position.[204] More women are affected by this condition than men, in a ratio of more than 3:1.[207]

Clinical findings include local tenderness of bony points, positive slump test, positive upper limb tension tests, depression or prominence of one or more spinous processes, and local thickening and stiffness of one segment,[207] although gross cervical and thoracic motions are usually normal.[203]

The differential diagnosis includes carpal tunnel syndrome, thoracic outlet syndrome (see Chapter 25), cervical disk disease, vascular disease, and neurologic disease.[203]

The intervention for this condition involves mobilization and manipulation of the involved segment, followed by an exercise progression emphasizing upper thoracic flexibility and muscle strength. Butler[206,208] recommends using both upper limb tension tests and also the slump test, with combinations of thoracic rotation and side bending.

Notalgia Paresthetica

The name of this condition comes from the Greek root meaning "pain in the back."[209] Clinically, this condition involves pruritus and localized dysesthesia and hyperesthesia in the distribution of one of the cutaneous posterior (dorsal) rami of the upper thoracic area.

The recommended intervention for this condition is an injection of corticosteroid.

THERAPEUTIC TECHNIQUES

The selection of a manual technique is dependent on a number of factors, including the acuteness of the condition and the restriction to the movement that is encountered. Of entimes, the same technique that was used to examine the segment can be used for the intervention, the difference being the intent of the clinician and the goal of the intervention. For example, if stretching of the mechanical barrier rather than pain relief is the immediate objective of the intervention, a mobilization technique is carried out at the end of the available range.

The antagonist muscle must be relaxed to achieve this, and this is most easily accomplished using a hold–relax technique. After this has been gained (and sometimes before and after), there is some minor pain to be dealt with, using grade IV oscillations, after which the joint capsule can be stretched, using either grade IV++ or prolonged stretch techniques. The prolonged stretch or the strong oscillations are continued for as long as the clinician can maintain good control. At the point where control is about to be lost, several isometric contractions to the agonists and the antagonists are demanded of the patient's muscles in the new range, to give the central nervous system information about the newly acquired range. To complete the reeducation, concentric and eccentric retraining is carried out throughout the whole range of the joint. Active exercises are continued at home and at work on a regular and frequent basis, to reinforce the reeducation.

Techniques to Increase Joint Mobility

Joint Mobilizations and High-Velocity Thrust Techniques

Mobilization and high-velocity thrust techniques have traditionally been used routinely in this region to[28,87,210,211]:

- restore thoracic mobility;
- reduce stresses through both the fixation and the leverage components of the spine;
- reduce stresses through the hypermobile segments; and
- reduce the overall force needed by the clinician, thus giving greater control.

CLINICAL PEARL

Cleland et al.[212] developed a clinical prediction rule (CPR) to identify a subgroup of patients with neck pain who

were considered more likely to benefit from a high-velocity thrust technique of the thoracic spine. However, more recent evidence has questioned its validity.[213] A recent study that included 24 consecutive patients,[214] tested two different forms of high-velocity thrust techniques to the thoracic spine based on this CPR. The study found that patients who were treated with a combination of cervical spine high-velocity thrust techniques and exercises showed significantly greater improvement in pain and disability compared to those treated with thoracic spine high-velocity techniques and exercises.

A number of studies have demonstrated clinical success with high-velocity thrust techniques to the thoracic spine.[127,131,215,216] However, it must be remembered that the isolation of a particular segment in the thoracic spine is extremely difficult, if not impossible, because of the number of articulations that exist at each segmental level. In addition, there are a number of concerns that the clinician must be aware of prior to considering using high-velocity thrust techniques in this region. T ese include the following:

- A number of studies have demonstrated that the meninges may be vulnerable to thoracic manipulative thrust techniques[217,218]
- T e narrow dimensions of the midthoracic spinal canal.
- T e poor blood supply to this region as compared to other areas of the spine.[51]
- T e potential fragility of the bones in this area due to such conditions as osteoporosis, and rheumatoid arthritis.

It is, therefore, recommended that the clinician performs the slump test (see Chapter 11) and a premanipulative hold (see Chapter 10) prior to any technique.

Long Sit Superior Distraction (T5–6). T e patient is positioned on the treatment table in the long sit position, with the buttocks on the edge of the back of the table and the hands on the back of the neck, fingers interlocked. T e clinician stands behind the patient and places a small towel roll at the T6 level. T e towel roll is held in place by the clinician's chest (made easier if the clinician turns slightly so that the side of the chest is used). T e clinician threads his or her arms under the patient's armpits and places the heel of the palms under the patient's forearms. T e patient is asked to flex the neck. A stride stance (one foot in front of the other) is adopted by the clinician (Fig. 27-23), and, while keeping the elbows close together, the clinician gently rocks the patient backward and forward. Af er two or three rocks, the traction force is applied, as the clinician shif s his or her body weight from the forward leg to the back, while lif ing the patient and pushing the patient's forearms toward the ceiling.

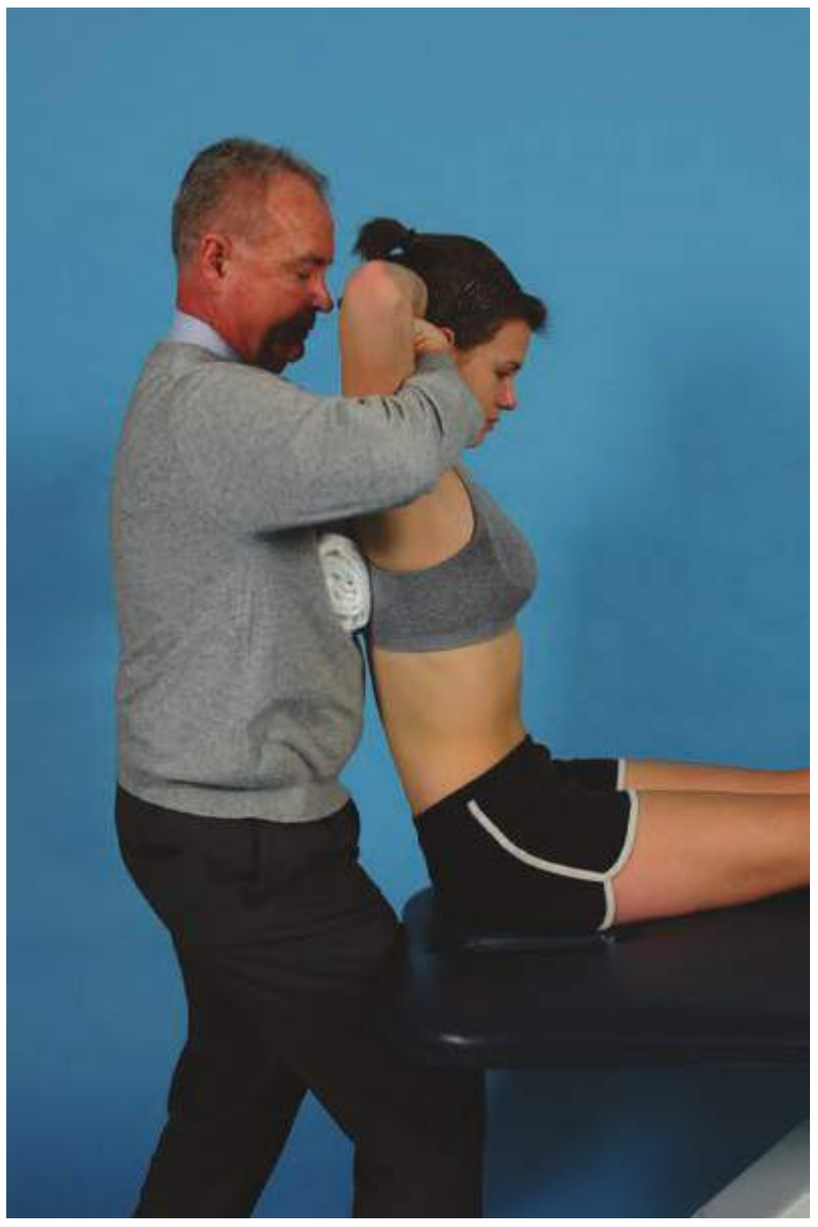

FIGURE 27-23 Long sit superior distraction thrust technique.

Exercises to Increase Soft-Tissue Extensibility

Shoulder Sweep

T is exercise is used to mobilize the chest wall and to integrate upper extremity function with thoracic spine and rib cage motion.[59]

T e patient is positioned supine on the floor or on a mat table, with the hips and knees flexed to about 90 degrees (Fig. 27-24). T e patient is asked to reach sideways and place the back of the hand as far out to the side as is comfortable. While maintaining contact with the floor, the patient moves the hand above the head and to the other side of the body, making a large circle around his or her body (see Fig. 27-24). Manual assistance applied to the scapula or rib cage can be used as can deep breathing, in order to move into the restricted ranges.

Thoracic Spine Flexion. T e patient kneels in front of a Swiss ball. T e patient positions themselves over the Swiss-ball so that weight is applied through the feet and the forearms (Fig. 27-25). While applying some body weight through the forearms, the patient arches the thoracic spine as far as is comfortable. T is position is held for 8–10 seconds, af er which the patient relaxes. T e exercise is repeated 8–10 times.

FIGURE 27-24 Shoulder sweep exercise.

FIGURE 27-25 Thoracic spine flexion over Swiss ball.

Thoracic Spine Extension. It is advised that the clinician monitor this exercise in case the patient loses his or her balance. The patient sits on a Swiss ball, with the feet on the ground. Once the patient has good sitting balance, he or she attempts to lie supine on the ball and then places the hands on the ball (Fig. 27-26). The patient is then instructed to move the top of the head toward the floor, in an attempt to fully extend the thoracic spine. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated 8–10 times. This exercise can be made more challenging by moving the hands from beside the body, out to the sides (Fig. 27-27) while maintaining the balance.

If the patient is unable to maintain his or her balance on the Swiss ball, a foam roll may be used. The foam roll also allows the clinician to focus the extension exercise on a specific segment.

Thoracic Spine Rotation. The following Swiss ball exercises to improve thoracic rotation range of motion and strength are recommended for the athletic population, only. The patient kneels with his or her back facing the Swiss ball. Using one leg at a time, the patient reaches back with the foot and places it on top of the Swiss ball. Once both feet are on the ball, the legs are straightened, and the weight of the body is primarily borne by the arms. Using the dorsum of the feet and the anterior legs, the patient induces a rotation of the thoracic region by twisting at the waist (Fig. 27-28), while maintaining balance through the arms. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated 8–10 times. By alternatively moving the legs into hip flexion and extension, rotation of the thoracic spine can be achieved, while maintaining balance with the arms (see Fig. 27-28).

FIGURE 27-27 Thoracic spine extension over Swiss ball—arms out to the side.

For the nonathletic population, thoracic rotation exercises can be performed using a firmer base of support. The patient kneels in front of a wobble board and places both hands on the board. Once good balance is achieved, the patient is asked to raise one arm out to the side as high as is comfortable, while keeping both knees on the floor. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated 8–10 times.

Thoracic rotation exercises can also be performed in the supine position. The patient lies supine with both knees bent and feet placed on the floor. The arms are abducted to

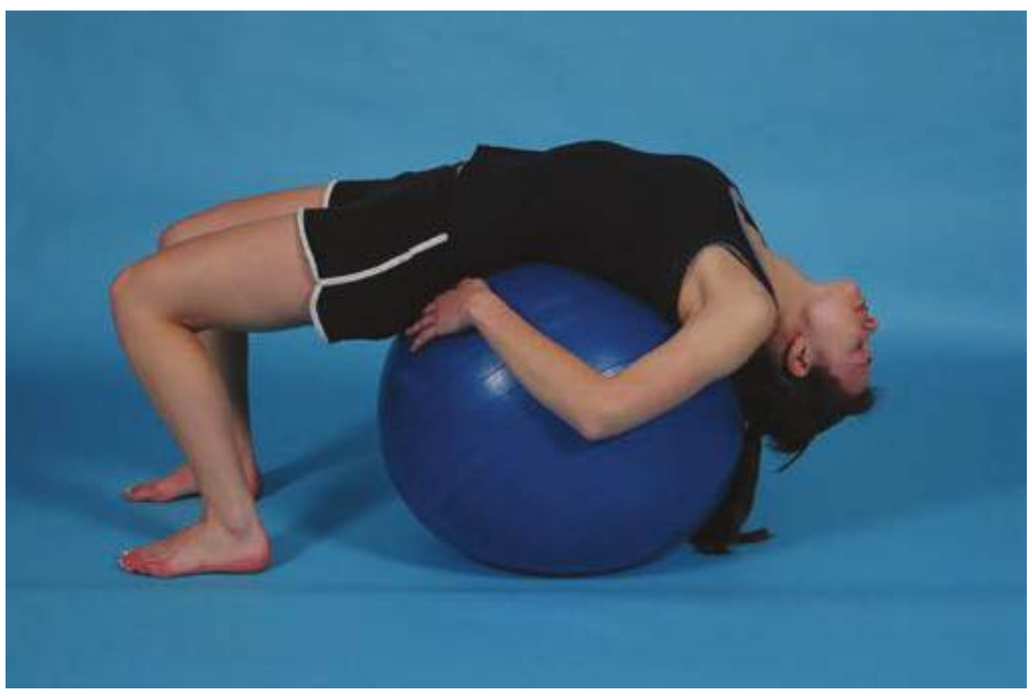

FIGURE 27-26 Thoracic spine extension over Swiss ball.

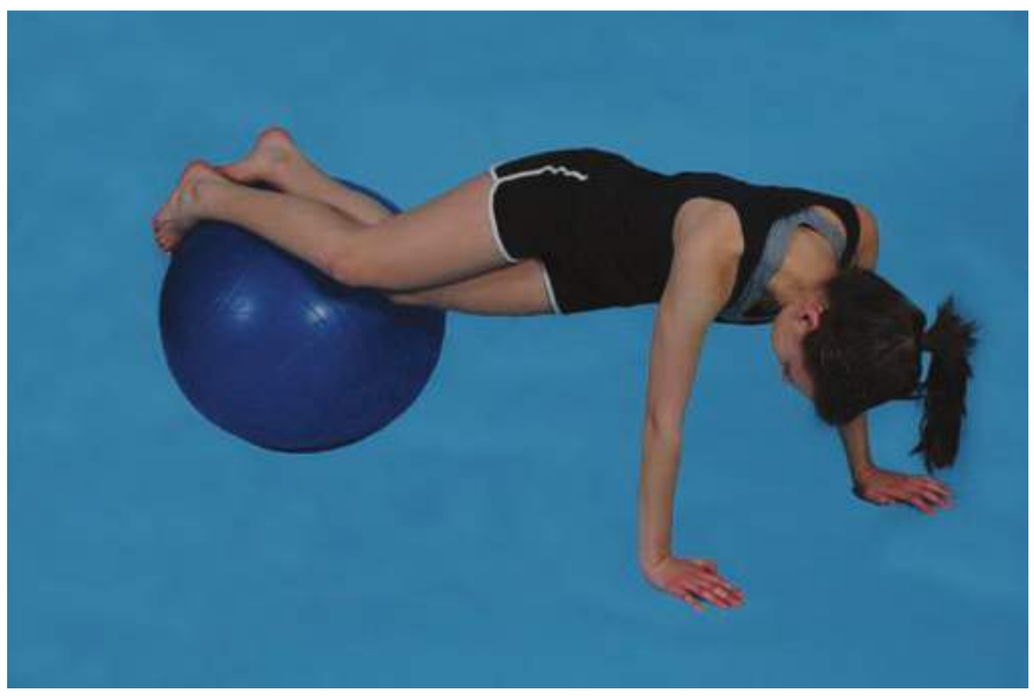

FIGURE 27-28 Thoracic spine rotation with trunk on Swiss ball.

FIGURE 27-29 Hook lying rotations with arms abducted.

FIGURE 27-30 Thoracic side bending over Swiss ball.

approximately 90 degrees (Fig. 27-29). Keeping the trunk against the floor, the patient lowers the thighs to one side and then the other (see Fig. 27-29), as far as is comfortable. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated 8–10 times.

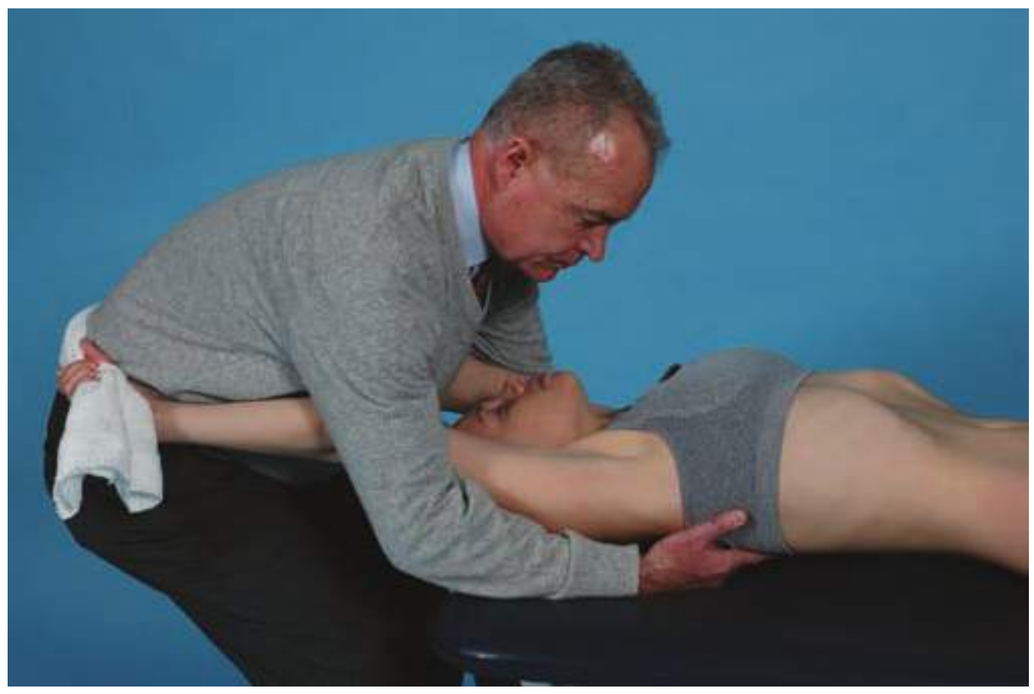

FIGURE 27-31 Supine myofascial stretch into extension.

Thoracic Spine Side Bending. The patient kneels to the side of a Swiss ball. The patient is asked to lean sideways over the ball and, with the arm closest to the ball, to attempt to touch the floor on the other side of the ball (Fig. 27-30) without losing balance. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated 8–10 times.

Rib Techniques for the Midlower Thoracic Spine

Myofascial Stretch into Extension. The patient is positioned supine, and the clinician stands at the head of the bed. The patient elevates both arms over the head and reaches around the back of the clinician's thighs. By having the patient hold a towel in this position, the clinician can place both of his or her hands under the patient's rib cage and pull the rib cage in an anterior and cranial direction, thereby encouraging thoracic extension (Fig. 27-31). A belt wrapped around the patient at the correct level can make this technique more specific.

CASE STUDY

RIGHT ANTERIOR CHEST PAIN

HISTORY

A 25-year-old man presented at the clinic complaining of pain in his right anterior chest. About 1 month previously, the patient had experienced a sudden and sharp pain in his right posterior chest at the midscapular level during a tug of war game at his company's picnic. The posterior chest pain subsided very quickly and did not bother him for the rest of the game. However, the next morning, pain was felt in the anterior aspect of the chest. This anterior chest pain eased off over the next few days with rest, but recurred as soon as the patient returned to weight lifting.[88]

Questions

1. Given the mechanism of injury, what structure(s) could be at fault?
2. Should the report of anterior chest pain concern the clinician in this case?
3. What is your working hypothesis at this stage? List the various diagnoses that could present with anterior chest pain and the tests you would use to rule out each one.
4. Why do you think the pain shift from posterior thoracic to anterior thoracic?
5. Does this presentation/history warrant a scan? Why or why not?

CASE STUDY

BiLaTeraL anD cenTraL Upper Thoracic pain

HISTORY

A 30-year-old housewife presents at the clinic with a 3-day history of constant central and bilateral upper thoracic pain that is deep and dull and can be felt in the front of the chest when the pain is aggravated. The pain is reported to be worse with flexion motions but is improved with lying on a hard surface. Further questioning revealed that the patient had a history of minor back pain but was otherwise in good health and had no report of bowel or bladder impairment.

Questions

1. What structure(s) could be at fault with central and bilateral upper thoracic pain as the major complaint?
2. Should the report of anterior chest pain concern the clinician in this case?
3. Why was the statement about "no reports of bowel or bladder impairment"pertinent?
4. What is your working hypothesis at this stage? List the various diagnoses that could manifest with central and bilateral upper thoracic pain and the tests you would use to rule out each one.
5. Does this presentation/history warrant a scanning examination? Why or why not?

CASE STUDY

neck Sprain

HISTORY

A 42-year-old right-handed female was referred by her primary-care physician with a diagnosis of neck sprain. The patient reported a 10-year history of intermittent neck pain (right greater than left), which had worsened over the past 6 months. More recently, the patient reported developing right shoulder (right upper trapezius) and arm pain, as well as infrequent (about twice a week) paresthesia in the right arm and hand involving the fourth and fifth digits. The patient described the pain as a sharp stabbing pain at the right side of the neck and a dull aching pain in the right upper trapezius region. She indicated that the neck pain was independent of the upper trapezius pain. At the time of the evaluation, the neck and upper trapezius pain were a 3/10 and 4/10, respectively. The symptoms improved when she positioned herself supine or left side lying with a pillow under the head. The upper trapezius pain was reduced when she side bent the head toward the side of pain and worsened as the day progressed, especially when she was at work and performing elevated arm activities. She reported that the paresthesias of the ulnar aspect of a right forearm, as well as digits 4 and 5, appeared more often during the afternoon and occasionally at night. When inquiring about the irritability of the condition, the patient reported that between a few hours and 1 day were required for the pain to decrease after it was provoked. The patient worked as a faculty member at a local college, which involved spending prolonged periods of time on the computer and extensive reading. The patient's past medical history was negative for dizziness, diplopia, unexpected weight change, drop attacks, dysarthria, dysphagia, tinnitus, and night pain unrelated to position.

Questions

1. List the structure(s) that could be at fault with these complaints.
2. Does this sound like a neuromusculoskeletal condition?
3. Are there any other questions you would ask this patient?
4. What is your working hypothesis at this stage? List the various diagnoses that could manifest with central and bilateral upper thoracic pain and the tests you would use to rule out each one.
5. Does this presentation/history warrant a scanning examination? Why or why not?

CASE STUDY

in Ter Sc a pULa r pa in

HISTORY

A 21-year-old woman presented with a 1-week history of left-sided interscapular pain that started at work. The patient worked as a computer operator. The pain was reported to be aggravated by lying prone, deep breathing in, and standing or sitting erect. Further questioning revealed that the patient had a history of this pain over the past few months but that it had not been as intense as it was currently. The patient was otherwise in good health and had no reports of bowel or bladder impairment.

Questions

1. List the structures that can produce interscapular pain.
2. Given the fact that this patient works at a computer, what could be the cause of her pain?
3. What is your working hypothesis at this stage? List the various diagnoses that could manifest with interscapular pain and the tests you would use to rule out each one.
4. Does this presentation/history warrant a scan? Why or why not?

CHAPTER 28 Lumbar Spine

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the lumbar intervertebral segment.
2. Outline the coupled movements of the lumbar spine, the normal and abnormal joint barriers, and the reactions of the various structures to loading.
3. Perform a detailed examination of the lumbar musculoskeletal system, including history, observation, palpation of the articular and soft-tissue structures, specific passive mobility and passive articular mobility tests for the intervertebral joints, and stability testing.
4. Evaluate the results of the examination and establish a diagnosis.
5. Describe the common pathologies and lesions of this region.
6. Describe intervention strategies based on clinical findings and established goals.
7. Design an intervention based on patient education, manual therapy, and therapeutic exercise.
8. Apply mobilization techniques for the lumbar spine, using the correct grade, direction, and duration, and explain the mechanical and physiologic effects.
9. Evaluate intervention effectiveness to progress or modify intervention.
10. Plan an effective home program, including spinal care, and instruct the patient in this program.
11. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

Over the past few decades, low-back pain (LBP) has become increasingly problematic, placing significant burdens on health systems and social-care systems.[1,2] Indeed, LBP is one of the most common disorders encountered by physical therapists.[3] The clinical course of LBP can be described as acute, subacute, recurrent, or chronic. The first episode of back pain can have differing results: 80–90% will be asymptomatic in 6 weeks, 98% in 24 weeks, and 99% in 52 weeks,[4] leading to the assumption that most cases of LBP are benign in nature.[5–7] However, the small percentage of people who do become disabled with chronic LBP account for 75–90% of the cost associated with LBP.[8] In addition, this population has been associated with a reduced quality of life, poor health, comorbidities, and high medical costs.[9,10] A number of risk factors have been associated with LBP. However, current literature does not support a definitive cause for the initial episode of LBP.[11]

ANATOMY

The lumbar spine (Fig. 28-1) consists of five lumbar vertebrae, which, in general, increase in size from L1 to L5 to accommodate progressively increasing loads. Between each of the lumbar vertebrae are the intervertebral disks (IVDs).

VERTEBRAL BODY

The anterior part of each vertebra is called the vertebral body. The pedicles, which project from the posterior aspect of the vertebral body, represent the only connection between the posterior joints of the segment and the vertebral bodies, both of which deliver tensile and bending forces. Noticeably, the muscles that act on a lumbar vertebra pull downward, transmitting the muscular action to the vertebral body. This muscular action is borne through the pedicles, which act as levers, and thus are subjected to a certain amount of bending.[12] If the vertebral body slides forward, the inferior articular processes of that vertebra abut against the superior articular processes of the next lower vertebra and resist the slide.[12] These resistive forces are transmitted to the vertebral body along the pedicles.

The lamina (see Fig. 28-1) functions to absorb the various forces that are transmitted from the spinous and articular processes. The pars interarticularis connects the vertically

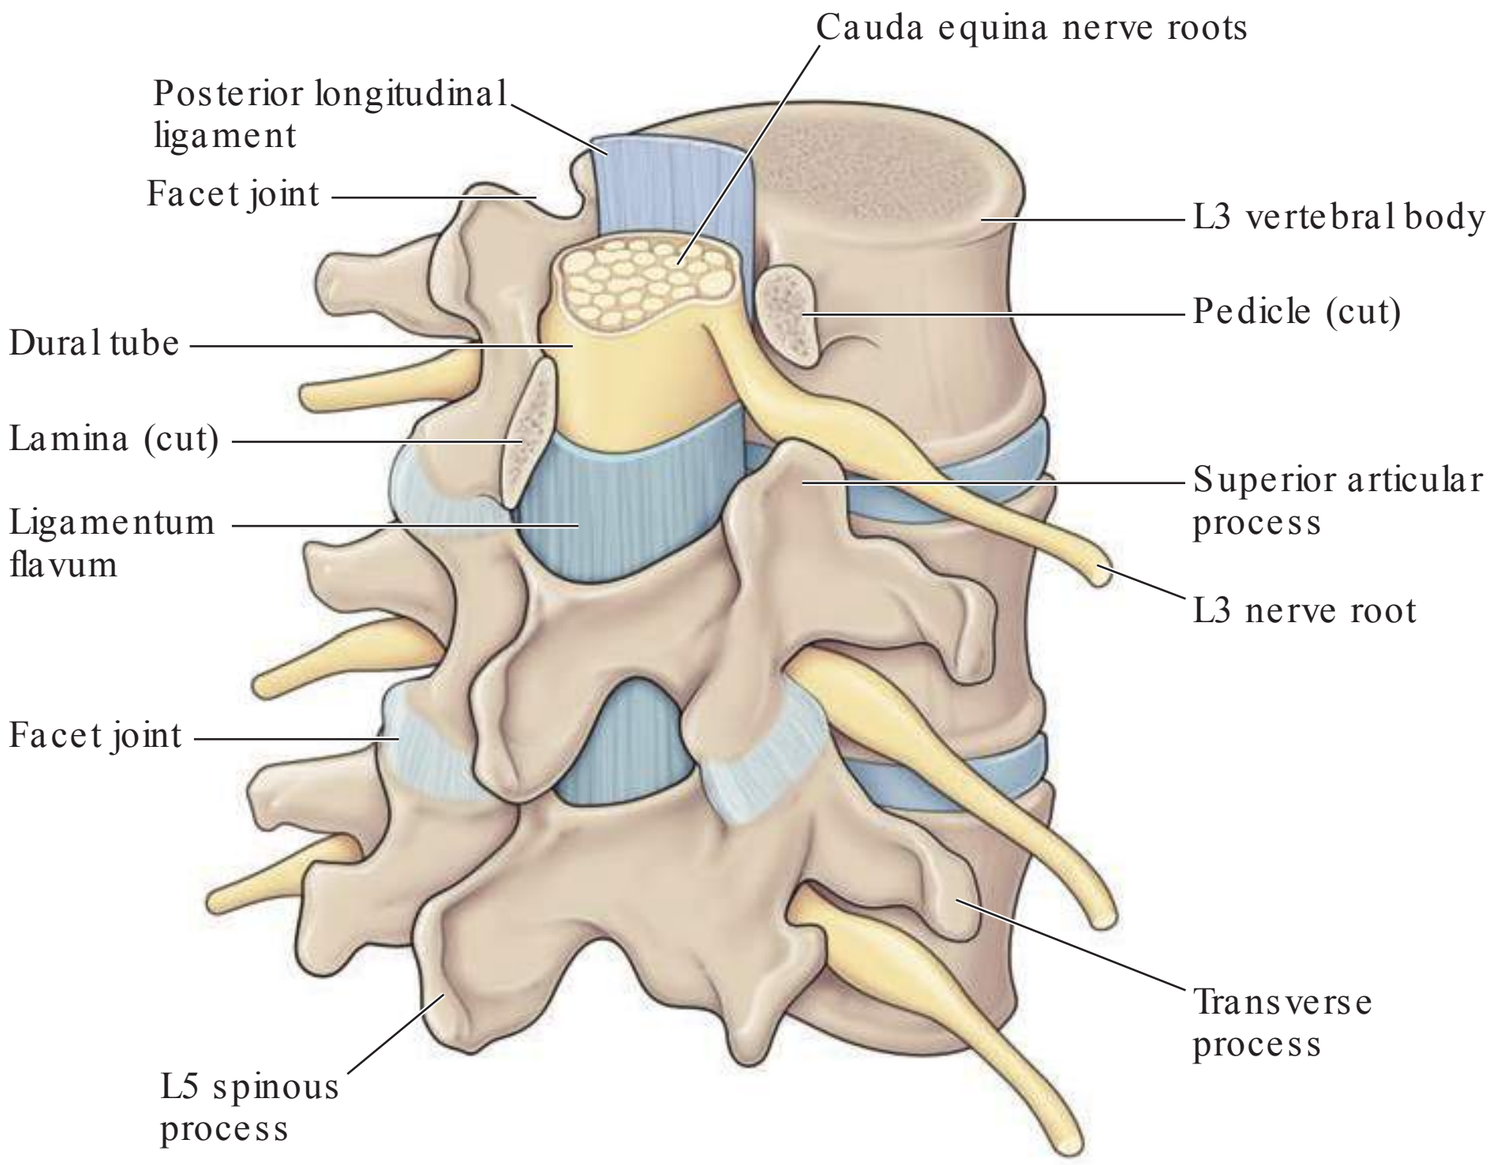

FIGURE 28-1 Structures of the lumbar spine.

oriented lamina and the horizontally extending pedicle, which exposes it to appreciable bending forces.[12] T e two laminae meet and fuse with one another, forming an arch of bone aptly called the vertebral, or neural arch, which serves as a bony tunnel for the spinal cord. Both the transverse and the spinous processes of the vertebral body provide areas for muscle attachments.

T e first sacral segment, the point at which the sacrum joins the lumbar spine, is usually included in discussions of the lumbar spine. In most cases, this is a fixed segment but, in some cases it may be mobile (lumbarization of S1). At other times, the fifth lumbar segment may be fused to the sacrum or ilium, resulting in a sacralization of that vertebra. It is unclear how these anomalies affect the biomechanics of the spine.

Intervertebral Disk

Annulus Fibrosus

In the lumbar spine, the superior and inferior surfaces of the vertebral bodies are comparatively large and flat, reflecting their load-transfer function. T e lumbar disk is approximately cylindrical, its shape being determined by the integrity of the annulus fibrosus (AF). T e AF consists of approximately 10–12 (often as many as 15–25) concentric sheets of predominantly type I collagen tissue,[13] bound together by proteoglycan gel.[14] T e number of annular layers decreases with age, but there is a gradual thickening of the remaining layers.[15] T e fibers of the AF are oriented at approximately 65 degrees from vertical. T e fibers of each successive sheet or lamella maintain the same inclination of 65 degrees, but in the opposite direction to the preceding lamella, resulting in every second sheet having the same orientation. T us, only 50% of the fibers are under stress with rotational forces at any given time. T is alteration in the direction of fibers in each lamella is vital in enabling the disk to resist torsional (twisting) forces.[16]

Although each lamella is thicker anteriorly than posteriorly, the lumbar disks are thinner and more tightly packed, posteriorly than anteriorly.[17] Consequently, the posterior part of the annulus will have thinner but stronger fibers, and it is capable of withstanding tension applied to this area during flexion activities and postures, which occur more frequently than with extension.[12] However, because of the predominance of flexion activities in life, fatigue damage may occur in the posterior aspect of the disk, making it a common site of injury.[18] T e wedge-shaped appearance of the disk produced by the configuration of the lamellae contributes to the normal lordosis of this region.[18]

T e outermost lamellae insert into the ring apophysis of the upper and lower vertebrae by mingling with the periosteal fibers (fibers of Sharpey). T ese fibers, attaching them to the bone, may be considered as ligaments and as such are designed primarily to limit motion between adjacent vertebrae.[19] T e inner portions of the lamellae are attached to the superior and inferior cartilaginous end plates, and form an envelope around the NP.[12]

Nucleus Pulposus

T e lumbar IVDs of a healthy young adult contain a nucleus pulposus (NP) that is composed of a semifluid mass of mucoid material. T is material is clear, firm, and gelatinous.[12]

CLINICAL PEARL

The overall consistency of the NP changes with increasing age, as the water content of the NP diminishes and subsequently becomes drier.

At birth, the water content of the NP is approximately 80%. In the elderly, the water content is approximately 68%. Most of this water content change occurs in childhood and adolescence, with only approximately 6% occurring in adulthood.[20] The portion of the NP that is not water is made up of cells that are largely chondrocytes and a matrix consisting of proteoglycans, collagen fibers, other noncollagenous proteins, and elastin.[18,21,22]

With the exception of early youth, there is no clear boundary between the NP and AF, and it resembles a transitional zone.[23] The biomechanical makeup of the NP is similar to that of the AF, except that the NP contains mostly type II collagen, as opposed to type I.[13] The collagen interacts with the ground substance to form a concentration proportional to the viscoelastic requirements of the AF.

CLINICAL PEARL

The IVDs are able to distribute compressive stress evenly between adjacent vertebrae because the NP and inner AF act like a pressurized fluid, in which the pressure does not vary with location or direction.[24,25] Biomechanical studies of the IVD seem to indicate that the disk acts to provide flexibility to low loads and stability at high loads.[26,27]

An unequal load distribution to the IVD is a major predisposing factor in radial tearing of the AF.[28] The tearing can be caused by the torsional effect of the superior vertebra rotating in a constant direction with sagittal movements. The posterolateral aspect of the AF tends to weaken first.[29] If the inner layers of the posterior AF tear in the presence of the NP that is still capable of bulging into the space left by the tear, the symptoms of disk disease are likely to be experienced, with the spinal canal location of disk trespass determining the type of neural compromise, clinical pain pattern, and often the outcome.[29] It must be remembered that the degree of neural compromise and potential for pain cannot be judged accurately by the size or type of disk material. Large, free fragments can often cause no neurologic deficit or pain.[30]

Vertebral End Plates

Each vertebral end plate consists of a layer of hyaline and fibrocartilage approximately 0.6–1-mm thick,[31] which covers the top or bottom aspects of the disk and separates the disk from the adjacent vertebral body. Peripherally, the end plate is surrounded by the ring apophysis.[12]

At birth, the end plate is part of the vertebral body growth plate, but by approximately the 20th year, it has been separated from the body by a subchondral plate. During this time, the plate is bilaminar, with a growth zone and an articular area.[32] With aging, the growth zone becomes thinner and disappears, leaving only a thickened articular plate.

Nutrition of the disk comes via a diffusion of nutrients from the anastomosis over the AF and from the arterial plexi underlying the end plate. Although almost the entire AF is permeable to nutrients, only the center portions of the end plate are permeable. Over approximately 10% of the surface of the end plate, the subchondral bone of the centrum is deficient. At these points, the bone marrow is in direct contact with the end plate, thereby augmenting the nutrition of the disk and end plate.[33] It is possible that a mechanical pump action produced by spine motion could aid with the diffusion of the nutrients.

The two end plates of each disk, therefore, cover the NP in its entirety but fail to cover the entire extent of the AF.

CLINICAL PEARL

Because of the attachment of the AF to the vertebral end plates on the periphery, the end plates are strongly bound to the IVD. In contrast, the vertebral end plates are only weakly attached to the vertebral bodies[34] and can be completely torn from the vertebral bodies by trauma. It is for this and other morphologic reasons that the end plates are regarded as constituents of the IVD, rather than as a part of the lumbar vertebral body.[32]

Between the ages of 20 and 65 years, the end plate thins and the vascular foramina in the subchondral bone become occluded, resulting in decreased nutrition to the disk. At the same time, the underlying bone becomes weaker, and the end plate gradually bows into the vertebral body, becoming more vulnerable centrally, where it may fracture into the centrum.[12] The presence of damage to a vertebral body end plate reduces the pressure in the NP of the adjacent disk by up to 57%, and doubles the size of the so-called stress peaks in the posterior aspect of the AF.[24]

Nerve Root Canal

The nerve root canal is located at the lateral aspect of the spinal canal (Fig. 28-1). The dural sac forms the medial wall of the canal, the internal aspect of the pedicle, and the lateral wall. The posterior border of the nerve root canal is formed by the ligamentum flavum, superior articular process, and lamina. The anterior border of the canal is formed by the vertebral body and IVD.

The nerve root canal can be described according to its location[35]:

- The entrance zone is medial and anterior to the superior articular process.
- The middle zone is located under the pars interarticularis of the lamina and below the pedicle.
- The exit zone is the area surrounding the intervertebral foramen.

A decrease in the dimension of this canal results in a condition called lateral stenotic syndrome.[36]

Innervation

The outer half of the IVD, the posterior longitudinal ligament (PLL), and the dura are innervated by the sinuvertebral nerve,[37] which is considered to arise from the anterior (ventral) ramus and the sympathetic trunk.[38] The nerve endings are simple or complex, are encapsulated and nonencapsulated, and exist as free nerve endings. It has been suggested that apart from a nociceptive function, these nerve endings may also have a proprioceptive function.[39,40]

Alterations in Disk Structure

Although the lumbar IVD appears destined for tissue regression and destruction, it remains unclear why similar age-related changes remain asymptomatic in one individual yet cause severe LBP in others. T e basic changes that influence the responses of the disk to aging appear to be biochemical and may concern the collagen content levels in the NP. Recently, advances in brain and spine imaging have begun to yield encouraging findings of a number of central and peripheral mechanisms thought to be important components of the generation and propagation of LBP.[41–43] Among these hypothesized mechanisms is an increase in diffusion of water within various soft tissues of the spine, occurring in response to treatment and movement, which may be linked to pain reduction.[43] A recent study found that changes in the diffusion of water within the lumbar IVDs at the L1–2, L2–3, and L5–S1 levels appeared to be related to differences in within-session pain reports following a single treatment of spinal manipulative therapy.[43]

With aging, there is an increase in the collagen content of both the NP and the AF and a change in the type of collagen present.[44] T e elastic collagen of the NP becomes more fibrous, whereas the collagen of the AF becomes more elastic.[44] Eventually, they come to resemble each other. In addition, the concentration of noncollagenous proteins increases in the NP. T e change of the makeup of the collagen alters the biomechanical properties of the disk, making it less resilient, perhaps leading to changes from microtrauma.[44]

CLINICAL PEARL

In general, the IVD becomes drier, stiffer, less deformable, and less able to recover from creep with age.

It was traditionally thought that the loss of height that occurs with aging resulted from a loss in the height of the IVD. More recently, it has been demonstrated that between the ages of 20 and 70 years, the disk actually increases its height by approximately 10%, and that the loss of height with age is more likely to be caused by the erosion of the vertebral end plate.[45]

As the NP becomes more fibrous, its ability to handle compressive loading becomes more compromised, and more weight is taken by the AF, resulting in a separation of the lamellae and the formation of cavities within it.[44]

Zygapophyseal Joint

T e articulations between two consecutive lumbar vertebrae form three joints. One joint is formed between the two vertebral bodies and the IVD. T e other two joints are formed by the articulation of the superior articular process of one vertebra and the inferior articular processes of the vertebra above it. T ese latter joints are known as the zygapophyseal joints.

In the intact lumbar vertebral column, the primary function of the zygapophyseal joint is to protect the motion segment from anterior shear forces, excessive rotation, and flexion.[46] Additional functions include

- the production of spinal motions including coupling movements;
- a minimal restrictor of the physiologic movements of extension and side bending.[47]

From an anteroposterior perspective, the zygapophyseal joints of the lumbar spine appear straight, but when viewed from above, they are seen to be curved into a J or C shape. T eir orientation varies both with the level and with the individual subject.[48] It is thought that this orientation serves to restrict maximally anterior and rotary movements and that the C-shaped joints do better in preventing anterior displacement than the J-shaped joints, because of the curvature of the joint surfaces.[12,49] Both shapes competently prevent rotation. T e area of the zygapophyseal joints most involved in resisting anterior shear forces is the anteromedial part of the superior zygapophyseal joint. It is this area that is most vulnerable to fibrillation.[12] T e tangential splitting and vertical tearing of the cartilage that occur with aging are believed to reflect these forces and appear to be a part of the normal degeneration of the joint.[12]

CLINICAL PEARL

At the thoracolumbar junction, the morphologic configuration of the zygapophysial joints is extremely variable. In general, there is a change from a relatively coronal orientation at T10–11 to a more sagittal orientation at L1–3, before returning to the more coronal orientation at L5 and S1. Davis[50] compared the thoracolumbar junction to a carpenter's mortise and tenon joint, which, when approximated, would have the effect of impeding all motion except flexion.[50] This appears to be particularly true with respect to axial rotation, in which there is a high degree of torsional stiffness.[51,52]

A fibrous capsule surrounds the joint on all of its aspects except the anterior aspect, which consists of the ligamentum flavum (LF). Posteriorly, the capsule is reinforced by the deep fibers of the multifidus.[53] In lumbar extension, there is a potential for the posterior capsule to become pinched between the apex of the inferior facet and the lamina below. To prevent this, some fibers of the multifidus blend with the posterior capsular fibers and appear to keep the capsule taut.[54]

Superiorly and inferiorly, the capsule is very loose. Superiorly, it bulges toward the base of the next superior transverse process, whereas, inferiorly, it does so over the back of the lamina. In both the superior and the inferior poles of the joint capsule, there is a very small hole that allows the passage of fat from within the capsule to the extracapsular space.[55]

Within the zygapophyseal joints, three types of intraarticular meniscoids have been noted[12]:

1. A connective tissue rim
2. An adipose tissue pad
3. A fibroadipose meniscoid

It is thought that the function of these intraarticular meniscoids is to

- fill the joint cavity;
- increase the articular surface area without reducing flexibility; and
- protect the articular surfaces, as they become exposed during extreme flexion and extension.

T ese menisci have been inculpated in the cause of some types of LBP when they fail to return to their original position on recovery from a flexion or extension movement and block the joint toward the neutral position.[56]

Ligaments

Anterior Longitudinal Ligament

T e anterior longitudinal ligament (ALL) covers the anterior aspects of the vertebral bodies and IVD (Fig. 28-2). T e ALL extends from the sacrum along the anterior aspect of the entire spinal column, becoming thinner as it ascends.[57] T e ALL is connected only indirectly with the anterior aspect of the IVD by loose areolar tissue.[12] Some of the ligament fibers insert directly into the bone or periosteum of the centrum.[58] Because of these attachments, and the pull on the bone from the ligament, it is proposed that the anterior aspect of the vertebral body can become the site for osteophytes. T e remaining ligament fibers cover two to five segments, attaching to the upper and lower ends of the vertebral body.

T e ALL of the lumbar spine is under tension in a neutral position of the spine and functions to prevent overextension of the spinal segments. In addition, the ALL functions as a minor assistant in limiting anterior translation and vertical separation of the vertebral body.

T e ALL receives its nerve supply from recurrent branches of the gray rami communicantes.[59]

Posterior Longitudinal Ligament

T e PLL is found throughout the spinal column, where it covers the posterior aspect of the centrum and IVD (see Fig. 28-2). Its deep fibers span two segments, from the superior border of the inferior vertebra to the inferior margin of the superior. T ese fibers integrate with the superficial annular fibers to attach to the posterior margins of the vertebral bodies.[12] T e more superficial fibers span up to five segments. In the lumbar spine, the ligament becomes constricted over the vertebral body and widens out over the IVD. It does not attach to the concavity of the body but is separated from it by a fat pad, which acts to block the venous drainage through the basivertebral vein during flexion, as the ligament presses it against the opening of the vein. Although the PLL is rather narrow and is not as substantial as the ALL, it is thought to be important in preventing IVD protrusion.[60] Both the ALL and the PLL have the same tensile strength per unit area.[61]

T e PLL tends to tighten in traction and in posterior shearing of the vertebral body. It also acts to limit flexion over a number of segments, although because of its proximity to the center of rotation, it is less of a restraint than the LF.[57]

T e PLL is innervated by the sinuvertebral nerve.

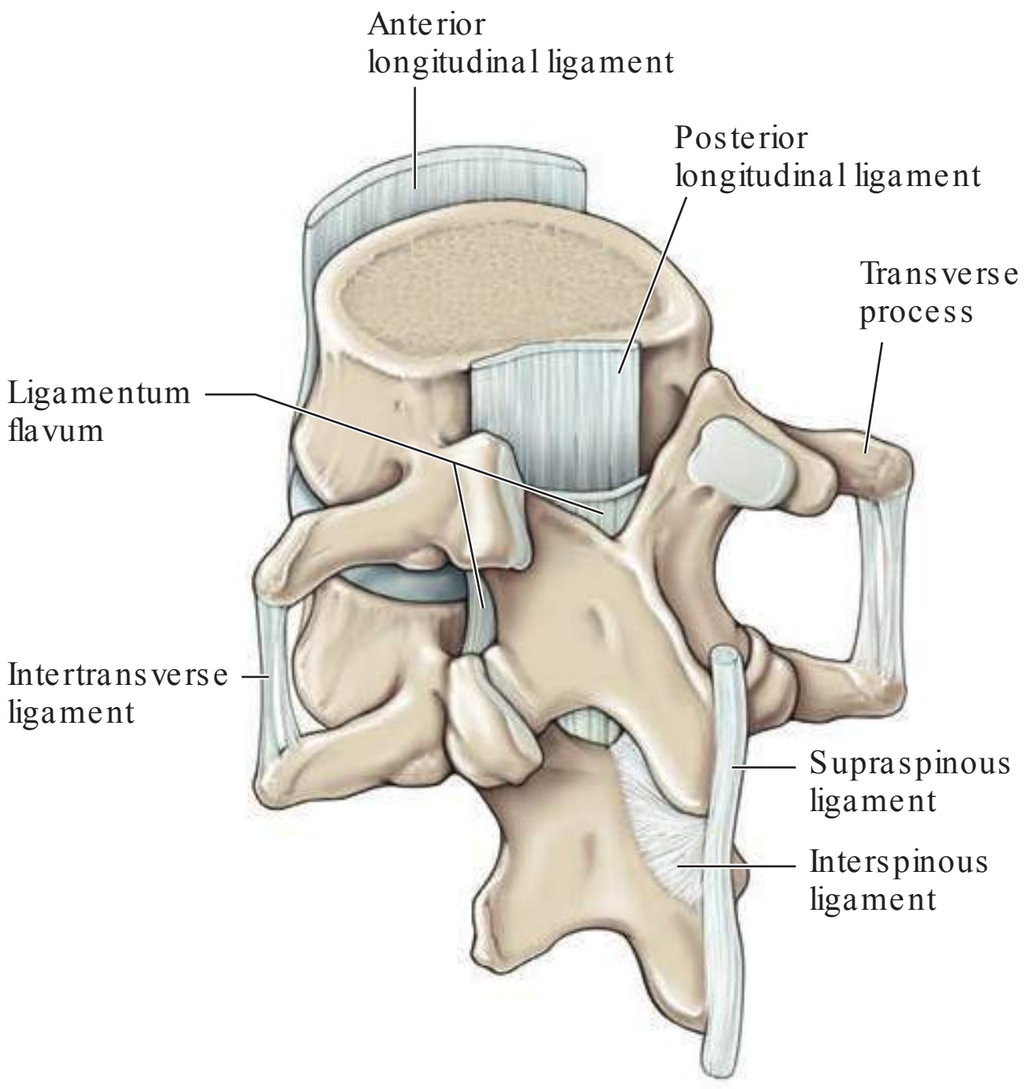

FIGURE 28-2 Ligaments of the lumbar spine. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Ligamentum Flavum

T e LF connects two consecutive laminae (see Fig. 28-2). T is is a bilateral ligament. T e medial aspect of the ligament attaches superiorly to the lower anterior surface of the lamina and the inferior surface of the pedicle.[62] T e LF attaches inferiorly to the back of the lamina and the pedicle of the next inferior vertebra.[62]

Its lateral portion attaches to the articular process and forms the anterior capsule of the zygapophyseal joint.

T e LF is formed primarily from elastin (80%), with the remainder (20%) being collagen.[63] T us, it is an elastic ligament that is stretched during flexion and recovers its neutral length with the neutral position, or extension.

T e function of the LF is to resist separation of the lamina during flexion, but there is also appreciable strain in the ligament with side bending.[12,64] Although it seems unlikely that the ligament contributes to an extension recovery from flexion, it does appear to prevent the anterior capsule from becoming nipped between the articular margins as it recoils during extension.[12] T e LF is innervated by the medial branch of the posterior (dorsal) ramus.[65]

Interspinous Ligament

T e interspinous ligament (see Fig. 28-2) lies deeply between two consecutive spinal processes. T e ligament is important for stability, as it represents a major structure for the posterior column of the spine. Unlike the longitudinal ligaments, it is not a continuous fibrous band but, instead, consists of loose tissue that fills the gap between the bodies of the spinous processes.[12,66] T e interspinous ligament is often disrupted in traumatic cases, which results in the posterior column becoming unstable. An extensive anatomic study on the interspinous ligament showed that degenerative changes start as early as the late second decade, with ruptures occurring in more than 20% of the subjects older than 20 years, particularly at L4–5 and L5–S1.[67]

T e ligament has three distinct parts—anterior (ventral), middle, and posterior (dorsal)—of which the middle has the most clinical significance, because it is the part where ruptures tend to occur.[66]

The interspinous ligament most likely functions to resist separation of the spinous processes during flexion.[68] This ligament is supplied by the medial branch of the posterior (dorsal) rami.[65]

Supraspinous Ligament

The supraspinous ligament (SSL) (see Fig. 28-2) is broad, thick, and cord like, but it is only well developed in the upper lumbar region.[12,69] Although it joins the tips of two adjacent spinous processes, the SSL is not considered by some to be a true ligament. This is because part of it is derived from the posterior part of the interspinous ligament, and because it also merges with the insertions of the lumbar posterior (dorsal) muscles.[66] Because this ligament is the most superficial of the spinal ligaments and the farthest from the axis of flexion, it has a greater potential for sprains.[70] The SSL is supplied by the medial branch of the posterior (dorsal) rami.[65]

Iliolumbar Ligament

The iliolumbar ligament is one of the three vertebropelvic ligaments, the others being the sacrotuberous and the sacrospinous ligaments. The ligament is variously believed to be a degenerate part of the quadratus lumborum or the iliocostalis and does not fully develop until approximately at the age of 30 years.[71]

The iliolumbar ligament functions to restrain flexion, extension, axial rotation, and side bending of L5 on S1.[72] Motions at the lumbosacral joint increase by approximately 20% in all directions when the ligament is missing or transected.[57] The incidences of degenerative instability and isthmic lumbar spondylolisthesis have also been shown to increase in its absence.[73,74]

Pseudoligaments

These ligaments, the intertransverse, transforaminal, and mamilloaccessory, resemble the membranous part of the fascial system separating paravertebral compartments and do not have any mechanical function.

Intertransverse Ligaments. These ligaments are more membranous than ligamentous. The ligament splits into posterior (dorsal) and anterior (ventral) portions, between which is a fat-filled recess. During flexion and extension movements, the fat can be displaced to accommodate the repositioning of the articular zygapophyseal joint. The main function of the ligament appears to be to compartmentalize the anterior and posterior musculature.[12]

Transforaminal Ligaments. Occurring in approximately 47% of subjects, the transforaminal ligaments traverse the lateral end of the intervertebral foramen.[75] The most significant of these ligaments is the superior corporotransverse ligament. At L5, the fifth lumbar nerve root runs between the ligament and the ala of the sacrum. With marked forward slip and downward descent of L5, or with a loss of IVD height, the corporotransverse ligament can have a guillotine effect on the fifth nerve root, resulting in symptoms that can mimic an IVD herniation or a foraminal occlusion.[76]

Mamilloaccessory Ligament. This ligament runs from the accessory process of one vertebra to the mammillary process of the same vertebra.[77] The ligament forms a tunnel for the medial branch of the posterior (dorsal) ramus, thereby preventing it from lifting off the neural arch. In approximately 10% of adults, the tunnel becomes ossified.[77]

Muscles

Quadratus Lumborum

The quadratus lumborum muscle is large and rectangular, with fibers that pass medially upward. The fibers attach to

- the anterior inferior surface of the 12th rib;
- the anterior surface of the upper four transverse processes;
- the anterior band of the iliolumbar ligament; and
- the iliac crest lateral to the attachment of the iliolumbar ligament.

The muscle is active during inspiration, fixing the lowest rib to afford a stable base from which the diaphragm can act. The importance of this muscle from a rehabilitation viewpoint is its contribution as a lumbar spine stabilizer.[78] Working unilaterally, it is typically involved with side bending of the lumbar spine, especially with eccentric control of contralateral side bending. The quadratus lumborum is an important, yet often underappreciated, lateral lumbar spine stabilizer that has been shown to be very active in sustained postures and when a heavy weight is held in the opposite hand.[79,80] The quadratus lumborum is supplied by the anterior (ventral) rami of T12–L4.[81,82]

Multifidus

The lumbar multifidus is the largest of the intrinsic back muscles to cross the lumbosacral junction and lies most medially in the spinal gutter (Fig. 28-3).[54] It is a fascicular muscle, with each fascicle being layered on another, giving it a laminated appearance.[12] The lumbar multifidus originates in three groups, which arise from the same vertebra.

1. Laminar fibers arise from the inferoposterior edge of the lamina.
2. Basal fibers arise from the base of the spinous process.
3. Common tendon fibers arise from a common tendon attached to the inferior tip of the spinous process.

The lumbar multifidus has a complicated insertion (Table 28-1).

Over the past several decades, there has been much research regarding the lumbar multifidus, with particular reference to its relationship to LBP, and its importance in lumbar spine stabilization. In vitro biomechanical studies have shown that the lumbar multifidus is an important muscle for lumbar segmental stability through its ability to provide segmental stiffness and to control motion.[83–85] Wilke et al.[86] concluded that the multifidus is responsible for two-thirds of the stiffness of the lumbar spine. The multifidus is active in nearly all antigravity activities and appears to contribute to the stability of the lumbar spine by compressing the vertebrae together.[44] Hides et al.[87] found reductions in ipsilateral multifidus cross-sectional area in patients with unilateral LBP and speculated that this may be a direct result of reflex inhibition.[88] This loss of multifidus cross-sectional area was shown to persist after

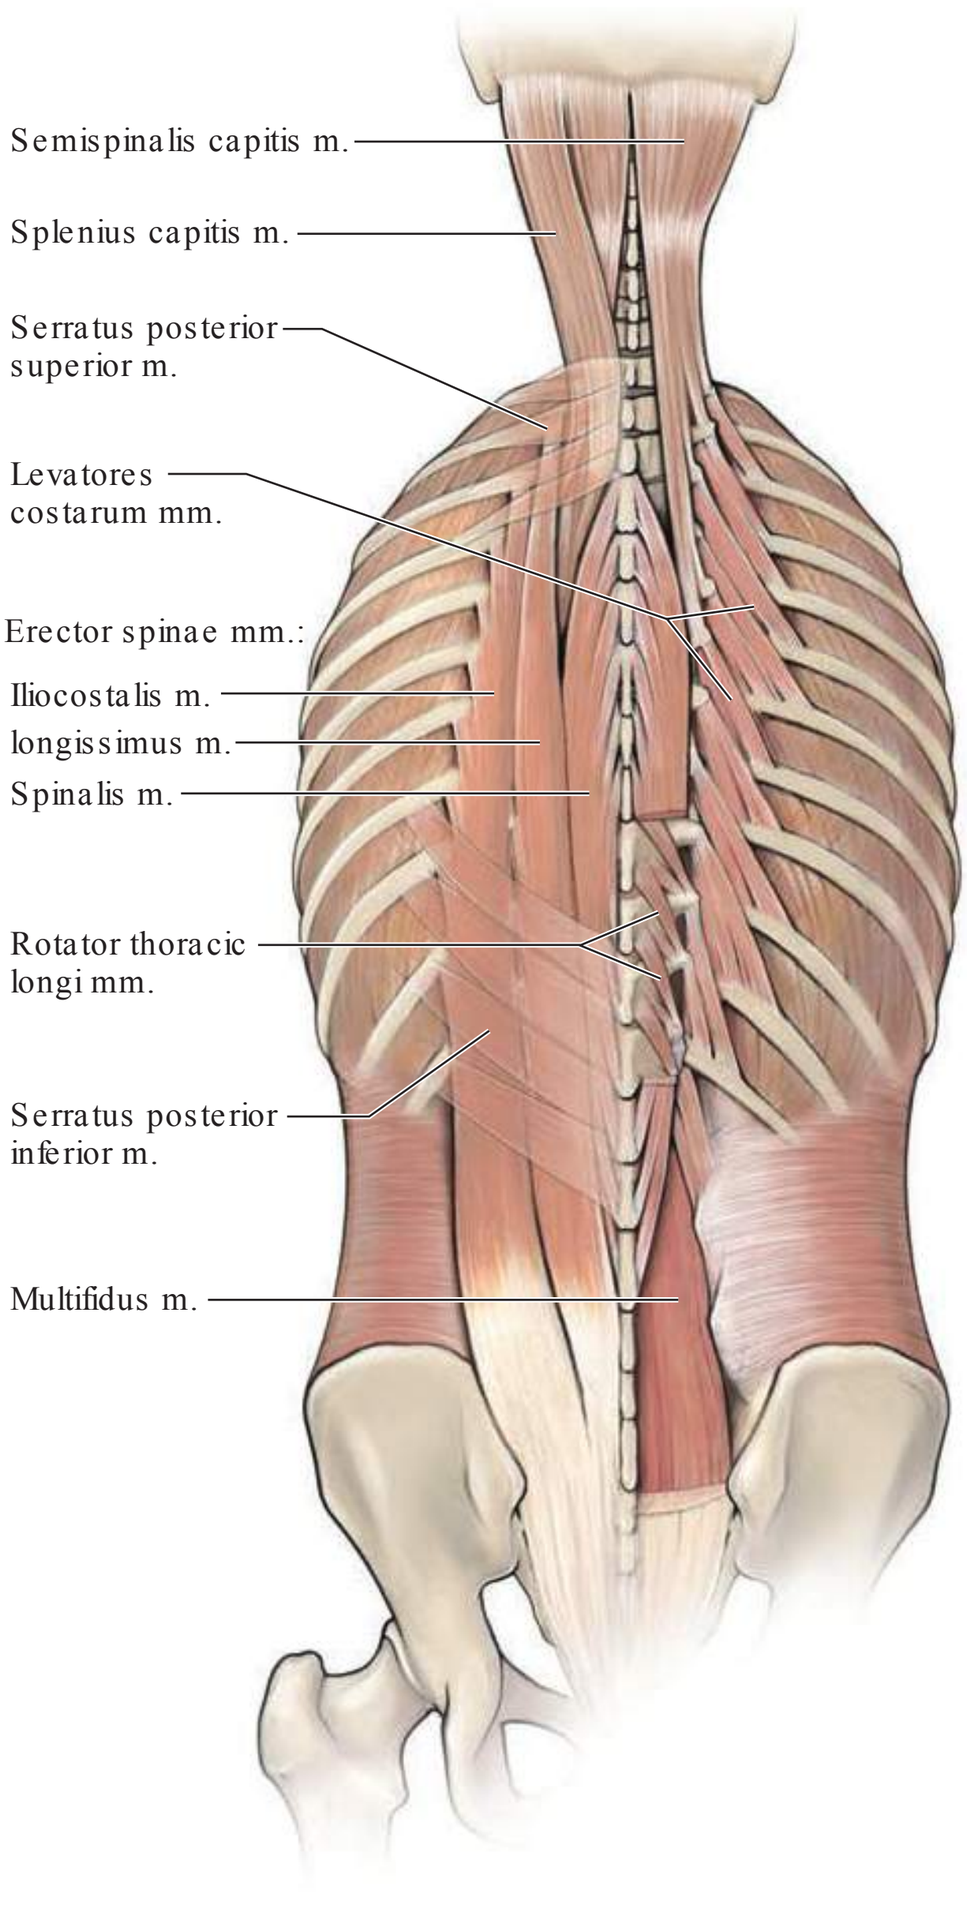

FIGURE 28-3 Multifidus and erector spinae. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

remission of LBP.[82] Isolated multifidus strengthening has been shown to restore the muscle size at the segmental level of the dysfunction.[88]

MacIntosh and Bogduk[54] analyzed the lumbar multifidus to determine the possible actions of the muscle and its individual fibers. The study revealed that when working bilaterally, the multifidus muscles can produce the rocking component of extension, but because of the muscle's vertical orientation, it cannot produce the accompanying translation.[54] In addition, the muscle, by "bow stringing" over a number of segments, can increase the lumbar lordosis, working in a postural role.[89]

Although not considered a primary lumbar rotator,[90] the multifidus is consistently active during both ipsilateral and contralateral spinal rotation, and both multifidi are simultaneously active regardless of which way the spine is

TABLE 28-1 Multifidus Attachments

Laminar	Basal	Common Tendon

Anatomy and biomechanics of the lumbar spine. In: Bogduk N, Twomey LT, eds. Clinical Anatomy of the Lumbar Spine and Sacrum. 3rd ed. Edinburgh: Churchill Livingstone; 1997: 2–53, 81–152, 171–176.

turning.[54,55] The major function of the multifidus from a biomechanical perspective is one of arthrokinematic control. It is believed that the lumbar multifidus acts as an antagonist to flexion and opposes the flexing moment of the abdominals as they rotate the trunk.[54,89,91] This is synergistic function may be compromised with an injury to the multifidus. Using magnetic resonance imaging (MRI), the signal intensities of the multifidus during lumbar hyperextension have been found to be markedly diminished in patients with chronic LBP compared with normal patients.[92]

Unilaterally, the multifidus muscle should also be able to produce side bending. However, its horizontal vector is very small, and it is unlikely to be an efficient side bender of the spine.[12,54]

The multifidus shares a close association with the gluteus maximus and the sacrotuberous ligament, factors that are thought to enhance sacroiliac joint and lumbar spine stability.[93–95]

The lumbar multifidus has the distinction of being innervated segmentally by the medial branch of the posterior (dorsal) ramus of the same level or the level below the originating spinous process.[96,97] Because the multifidus is segmental in origin and innervation, any impairment of this muscle can produce palpable changes in the muscle, thus directing the clinician to the segment that is dysfunctional.[98]

Erector Spinae

The erector spinae is a composite muscle consisting of the iliocostalis lumborum and the thoracic longissimus (Fig. 28-3). Both of these muscles are subdivided into the lumbar and thoracic longissimi and iliocostallii.[12] As a group, the muscles of the erector spinae play an important role in lumbar stabilization by providing compressive forces along the spine that stabilize the spinal curvatures.[99] The nerve supply to the erector spinae muscles is by the medial branch of the posterior (dorsal) ramus of the thoracic and lumbar spinal nerves.

Longissimus Thoracis Pars Lumborum. This is a fascicular muscle that arises from the accessory processes of the lumbar vertebrae to insert into the posterior-superior iliac spine

(PSIS) and the iliac crest lateral to it. The upper four tendons converge to form the lumbar aponeurosis that inserts laterally to the L5 fascicle.

The longissimus thoracis pars lumborum muscles have both a vertical and a horizontal vector. The vertical vector is much the larger of the two and can produce extension or side bending, depending on whether it is functioning bilaterally or unilaterally.[100] Because of its attachment to the transverse rather than the spinous process, which results in reduced leverage, the longissimus thoracis pars lumborum is much less efficient than the lumbar multifidus in producing posterior sagittal rotation.[97,101] Indeed, mathematical analysis of the lumbosacral portion of the muscle suggests that the net effect of its pull would be to produce an anterior, and not a posterior, shear.[12]

Iliocostalis Lumborum Pars Lumborum. There are four overlying fascicles arising from the tip of the upper four transverse processes and the adjoining middle layer of the thoracolumbar fascia (TLF). The fibers insert onto the iliac crest, with the lower and deeper fibers attaching lateral to the PSIS.[101]

There is no muscular fiber from L5, but it is believed that this is represented by the iliolumbar ligament, which is completely muscular in children, becoming collagenous by approximately 30 years of age.

The vectors and actions of this muscle are similar to those of the longissimus. However, the lower and deeper fibers produce strong axial rotation and act with the multifidus as synergists to produce rotation during abdominal muscle action.[101]

Longissimus Thoracis Pars Thoracis. This muscle group consists of 11–12 pairs of muscles, which extend from the transverse processes of T2 and their ribs, and run inferomedially to attach to the spinous processes of L3–5 and the sacral spinous processes, as well as the PSIS.

The orientation and various attachments of this muscle group allow it to act indirectly on the lumbar spine. The main action of the muscle appears to be the extension of the thoracic spine on that of the lumbar. An anatomic-mathematical study[102] suggests that 70–80% of the force required to extend the upper lumbar spine is produced from the thoracic fibers of the erector spinae, which also generate 50% of the force at the lower levels.

Iliocostalis Lumborum Pars Thoracis. The thoracic iliocostalis serves as the thoracic part of the iliocostalis lumborum and not the iliocostalis thoracic. It is a layered muscle consisting of inferomedially orientated fascicles attached to the following points[101]:

- lateral part of the lower eight rib angles;
- PSIS; and
- the posterior (dorsal) surface of the sacrum, distal to the multifidus.

This muscle completely spans the lumbar spine and is in an excellent position to extend and side bend the spine, as well as to increase the lumbar lordosis. It is a weak rotator because the amount of rib separation on ipsilateral rotation is minor, but on contralateral rotation, it is better. It is, therefore, possible that the muscle is an effective derotator of the spine.[12]

Abdominal Muscles

Rectus Abdominis. The rectus abdominis (Fig. 28-4) originates from the cartilaginous ends of the fifth through seventh ribs and xiphoid and inserts on the superior aspect of the pubic bone. The linea alba (Fig. 28-4) is the anterior abdominal aponeurosis or rectus sheath in the midline. It is formed by the interlacing of the aponeurosis of the external oblique, internal oblique (IO), and transverse abdominis (TrA) muscles from both sides. It is broader superiorly, where the recti are separated at a considerable interval, and narrower inferiorly, where the recti are closely packed (Fig. 28-4). Above the umbilicus, the linea alba is a single layer, whereas below the umbilicus it has a double layer.[103]

CLINICAL PEARL

A split between the two rectus abdominis to the extent that the linea alba may split under strain is known as a diastasis recti (see "Practice Pattern 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Localized Inflammation" section).[103–108]

The rectus abdominis muscle functions to produce torque during flexion of the vertebral column, as it approximates the thorax and pelvis anteriorly.[109] The muscle appears to serve a beneficial role in helping to stabilize the lumbar spine in the sagittal plane.[88]

Transversus Abdominis. The TrA muscle (Fig. 28-4) originates from the lateral one-third of the inguinal ligament, the anterior two-thirds of the inner lip of the iliac crest, the lateral raphe of the TLF, and the internal aspects of the lower six costal cartilages, where it interdigitates with the diaphragm.[110] Its upper and middle fibers run transversely around the trunk and blend with the fascial envelope of the rectus abdominis muscle, while the lower fibers blend with the insertion of the IO muscle on the pubic crest.[111] A number of differences in the fiber orientation of the upper, middle, and lower regions of the TrA have been noted[112]:

- Upper fibers: these fibers, which include the fibers from the sixth costal cartilage to the inferior border of the rib cage, have been found to be oriented superomedially.
- Middle fibers: these fibers, which include the fibers from the inferior border of the rib cage to a line connecting the superior borders of the iliac crest, have been found to be oriented inferomedially.
- Lower fibers: these fibers, which include those from the iliac crest and the pubic symphysis, were found to be oriented more inferomedially than the middle fibers.

Although much emphasis has traditionally been placed on the strengthening of the rectus abdominis during lumbar spine rehabilitation, attention has switched to the contraction of the hoop-like TrA that creates a rigid cylinder, resulting in enhanced stiffness of the lumbar spine and stabilization of the lumbar motion segment (see "Biomechanics" section).[2,79,113–116] Since the midportion of the TrA attaches to the cross-hatch arrangement of the middle layer of the TLF (see later), contraction of the TrA has been thought to increase spinal stability and a motor control via

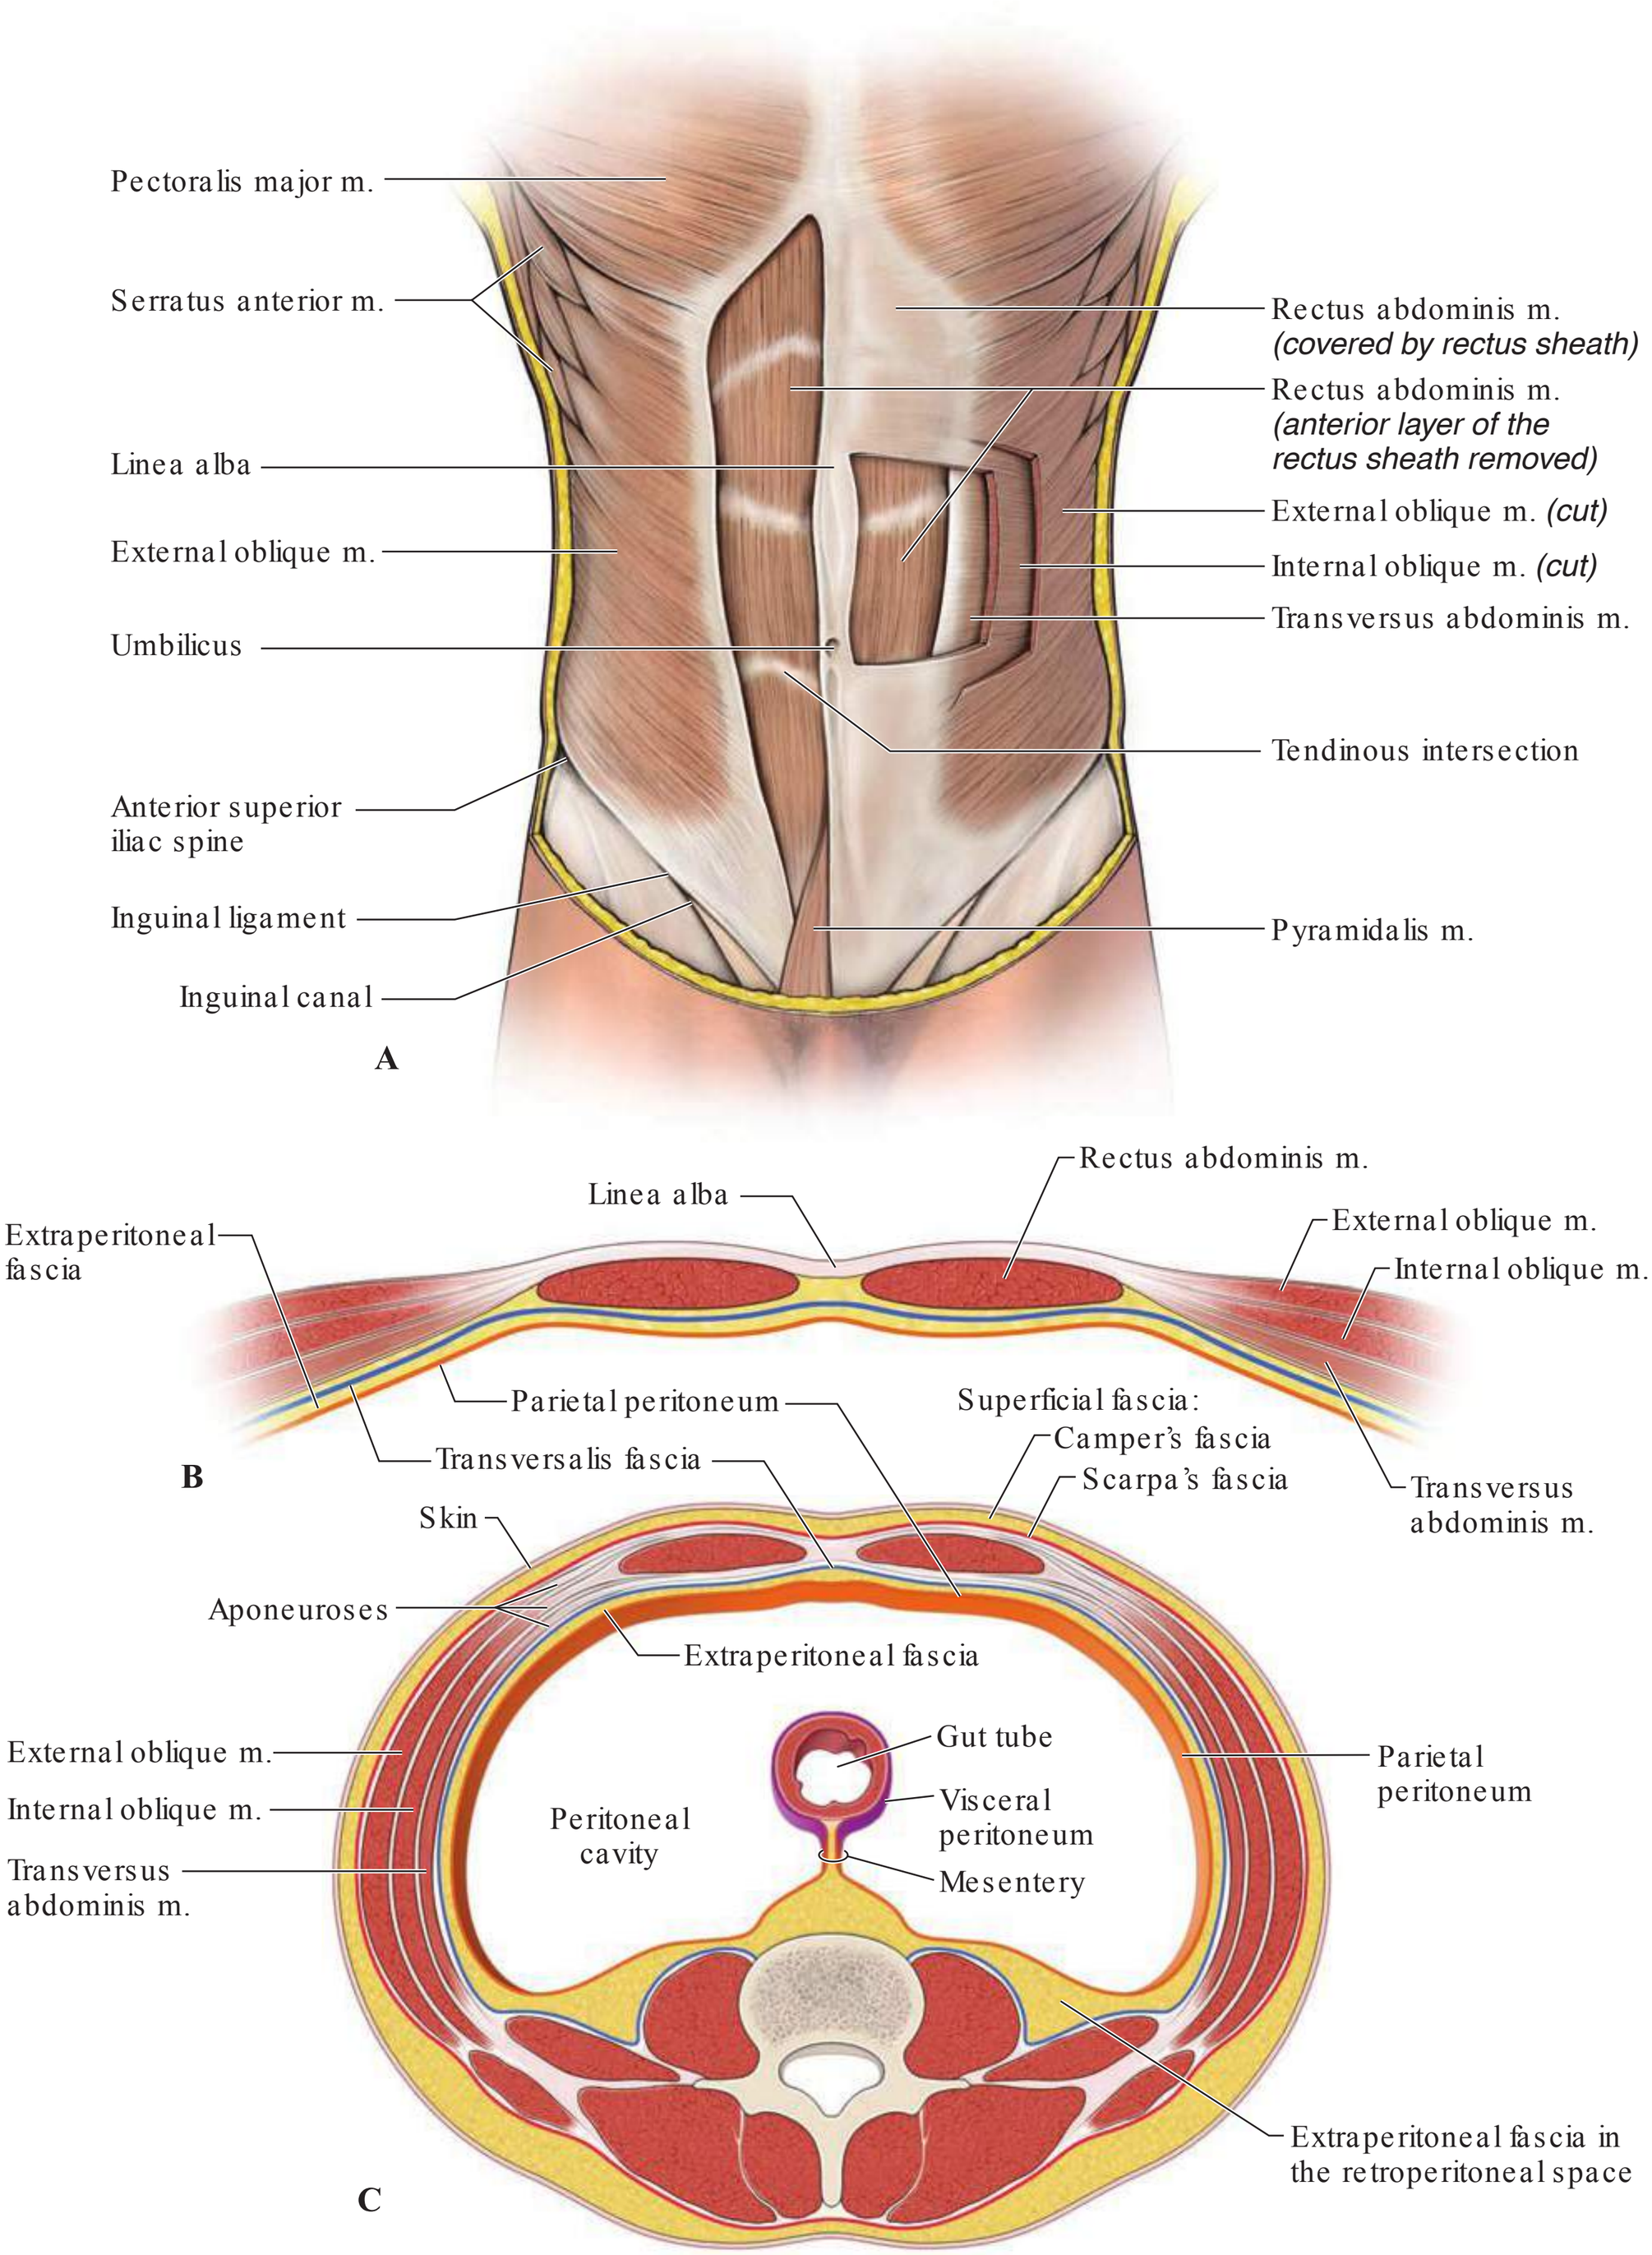

FIGURE 28-4 Abdominal muscles. (Reproduced, with permission, from Chapter 7. Anterior Abdominal Wall. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

tensioning of the TLF in the middle and lower regions of the lumbar spine or by producing a mild stabilizing compressive force on the lumbar vertebrae.[88,110,116] The TLF creates a pressurized visceral cavity anterior to the spine when the TrA contracts. This force is theorized to increase the stability of the lumbar spine during a variety of postures and movements.[117]

Internal Oblique. The IO (see Fig. 28-4), which forms the middle layer of the lateral abdominal wall, is located between the TrA and the external oblique muscles.[118] It has multiple attachments to the inguinal ligament, lateral raphe, iliac crest, pubic crest, TrA, and costal cartilages of the seventh through ninth costal cartilages. Because of these multiple attachment sites, the different fascicles of the muscle can have very different force vectors.

The IO is active during a number of functions, including gait (most often close to initial contact[119]) and erect sitting and standing postures.[120] Acting bilaterally, the IOs flex the vertebral column and assist in respiration. Acting in unison, the muscle, in conjunction with the external obliques, can produce rotation of the vertebral column, bringing the thorax backward (when the pelvis is fixed) or the pelvis forward (when the thorax is fixed).[109,121]

External Oblique. The external oblique (see Fig. 28-4) originates from the lateral aspect of the fifth through twelfth ribs, and through interdigitations with the serratus anterior and latissimus dorsi. The muscle travels obliquely, medially, and inferiorly to insert into the linea alba, inguinal ligament, anterior-superior iliac spine (ASIS), iliac crest, and pubic tubercle.

When acting bilaterally, the external obliques flex the vertebral column and tilt the pelvis posteriorly. Acting in unison, the muscle, in conjunction with the IOs, can produce side bending of the vertebral column, approximating the thorax and the iliac crest laterally.[109]

Researchers have suggested that the IOs, and to a lesser extent the external obliques, may contribute to the production of intraabdominal pressure and thus stability of the lumbar spine.[122]

Psoas Major

Although traditionally viewed as a muscle of the hip, the psoas major muscle combines with the iliacus muscle to directly attach the lumbar spine to the femur.[123] The psoas major originates from

- anterolateral aspects of the vertebral bodies;
- IVDs of T12–L5;
- transverse processes of L1–5; and
- tendinous arch spanning the concavity of the sides of the vertebral bodies.

The iliacus is attached superiorly to the iliac fossa and the inner lip of the iliac crest. Joining with the psoas major, the combined tendon passes over the superior lateral aspect of the pubic ramus and attaches to the lesser trochanter of the femur.

Taken individually, the iliacus and psoas major serve different functions.

- The psoas major is electromyographically active in many different positions and movements of the lumbar spine, and its activity can add a stabilizing effect on the lumbar spine with compressive loading.[124] With the foot fixed on the ground (closed chain), contraction of the psoas major increases the flexion of the lumbar-pelvic unit on the femur.[125]
- With the foot fixed on the ground, contraction of the iliacus produces an anterior torsion of the ilium and extension of the lumbar zygapophyseal joints. If there is a decrease in the length of the iliopsoas as a result of adaptive shortening or increased efferent neural input to the muscle, the result is an anteriorly rotated pelvis and an increase in lordosis. This may increase the anterior shear stress at the lumbosacral junction in any posture.[124]

From a clinical perspective, the iliacus and psoas major usually are considered together as the iliopsoas. Working bilaterally (insertion fixed), the iliopsoas can produce flexion of the trunk on the femur as in the sit-up from a supine position, or in bending over to touch one's toes. The iliopsoas muscle also side bends the spine ipsilaterally.[124]

Working from a stable spine above (origin fixed), the iliopsoas muscle flexes the hip joint by flexing the femur on the trunk.

The iliopsoas is innervated by the anterior (ventral) rami of L1 and L2.

Thoracolumbar Fascia

The TLF travels from the spinous process of T12 to the PSIS and iliac crest. The TLF consists of three layers of connective tissue that envelop the lumbar muscles and separate them into anterior, middle, and posterior compartments or layers[126]:

1. The anterior layer covers the anterior surface of the quadratus lumborum muscle. It is attached to the anterior transverse processes and then to the intertransverse ligaments. On the lateral side of the quadratus lumborum, it blends with the other layers of the fascia.
2. The middle layer is posterior to the quadratus lumborum, with its medial attachment to the tips of the transverse processes and the intertransverse ligaments. Laterally, it gives rise to, or is attached to, the transverse abdominal aponeurosis.
3. The posterior layer covers the lumbar musculature and arises from the spinous processes, wrapping around the muscles. It blends with the other layers of the fascia along the lateral border of the iliocostalis lumborum in a dense thickening of the fascia called the lateral raphe.[126] This layer consists of two laminae, a superficial one with its fibers orientated inferomedially, and a deep lamina whose fibers are inferolateral. The superficial fibers are derived from the latissimus dorsi.

The functions of the TLF are varied. The TLF

- provides muscle attachment for the transversus abdominis;
- stabilizes the spine against anterior shear and flexion moments;
- resists segmental flexion via tension generated by the TrA on the spinous process; and

- assists in the transmission of extension forces during lifting activities. The posterior ligamentous system has been proposed as a model to explain some of the forces required for lifting. It is believed to transmit forces by passive resistance to flexion, from the joint capsule and extracapsular ligaments, and from the more dynamic effects of the TLF.[127]

Lumbopelvic Fascia

The lumbopelvic fascia connects the proximal structures of the trunk to the hip girdle. The TrA, obliques, erector spinae, and multifidus all have attachments with the lumbopelvic fascia and connect the latissimus dorsi superiorly to the gluteal muscles inferiorly. It has been theorized that the lumbar fascia has a specialized function as an elastic structure storing energy from isometric actions of the latissimus dorsi and contralateral gluteus maximus during ambulation.[128] The latissimus dorsi and gluteus maximus are linked through this structure and provide a "pathway for uninterrupted mechanical transmission between pelvis and trunk" through muscular "slings."[129] Vleeming et al.[129] have proposed four sling systems[130]:

- The anterior oblique system, which is comprised of the external oblique, contralateral IO, and contralateral adductors. This system contributes to force closure of the pubic symphysis and sacroiliac joint.
- The posterior oblique system which is comprised of the latissimus dorsi, contralateral gluteus maximus, and TLF. This system contributes to the force closure of the sacroiliac joint and is a significant contributor to load transference through the pelvic girdle during rotational activities and gait. The fibers of the latissimus dorsi and contralateral gluteus maximus are in line with each other, and perpendicular to the sacroiliac joint, providing external support.
- The deep longitudinal system, which is comprised of the erector spinae, sacrotuberous ligament, and multifidus, biceps femoris, fibularis (peroneus) longus, and anterior tibialis. This system is engaged when the foot is in contact with the ground and serves to transmit energy from the upper trunk through the thoracic or lumbar fascia and erector spinae muscles to the biceps femoris and the lower extremity musculature.
- The lateral system which is comprised of the gluteus medius and minimus, contralateral adductors, and contralateral quadratus lumborum. The muscles of this system provide essential frontal plane stability by indirectly facilitating pelvic girdle control during standing and ambulation.

Nerve Supply of the Lumbar Segment

The nerve supply to the lumbar spine follows a general pattern. The outer half of the IVD is innervated by the sinuvertebral nerve[37] and the gray rami communicantes,[131] with the posterolateral aspect innervated by both the sinuvertebral nerve[59] and the gray rami communicantes. The lateral aspect receives only sympathetic innervation.

The zygapophyseal joints are innervated by the medial branches of the posterior (dorsal) rami.[37,65,132] Each joint receives its nerve supply from the corresponding medial branch above and below the joint.[37,65] For instance, the L4–5 joint receives its nerve supply from the medial branches of L3 and L4. The lateral branches cross the subjacent transverse process and pursue a sinuous course inferiorly, laterally, and posteriorly through the iliocostalis lumborum.[65] They innervate that muscle, and eventually the L1–3 lateral branches pierce the posterior (dorsal) layer of TLF and become cutaneous, supplying the skin over the lateral buttock as far as the greater trochanter.[37,65] The intermediate branches run posteriorly and inferiorly from the intertransverse spaces. They form a series of intersegmental communications within the longissimus thoracis.[37,65]

At the L1 and L2 levels, the nerves exit the intervertebral foramen above the disk. From L2 downward, the nerves leave the dura slightly more proximally than the foramen through which they pass, and at a decreasing angle of obliquity and an increasing length of the spinal canal. The L3 nerve root travels behind the inferior aspect of the vertebral body and the L3 disk. The L4 nerve root crosses the whole vertebral body to leave the spinal canal at the upper aspect of the L4 disk, at an angle of approximately 60 degrees. The L5 nerve root emerges at the inferior aspect of the fourth lumbar disk at an angle of approximately 45 degrees and crosses the fifth vertebral body to exit at the upper aspect of the L5 disk. The S1 nerve root emerges at a 30-degree angle and crosses the L5–S1 disk.

Lumbar Spine Vascularization

The blood supply to the lumbar spine is provided by the lumbar arteries (Fig. 28-5), and its venous drainage occurs via the lumbar veins (Fig. 28-5).

BIOMECHANICS

Physiologic motions at the lumbar spine joints can occur in three cardinal planes: sagittal (flexion and extension), coronal (side bending), and transverse (rotation). Including accessory motions, six degrees of freedom are available at the lumbar spine.[60]

The amount of segmental motion at each vertebral level varies. Most of the flexion and extension of the lumbar spine occurs in the lower segmental levels, whereas most of the side bending of the lumbar spine occurs in the midlumbar area.[110,133,134] Rotation, which occurs with side bending as a coupled motion, is minimal and occurs most at the lumbosacral junction.[110,133,134] The amount of range available in the lumbar spine generally decreases with age.[135]

Flexion

The lumbar spine is well designed for flexion, which is its most commonly used motion in daily activities. Flexion of the lumbar spine from erect standing involves an unfolding or straightening of the lumbar lordosis, followed by, at most, a small reversal of the lordotic curve.[136] The flexion–extension range of the lumbar spine that occurs between vertebral segments is

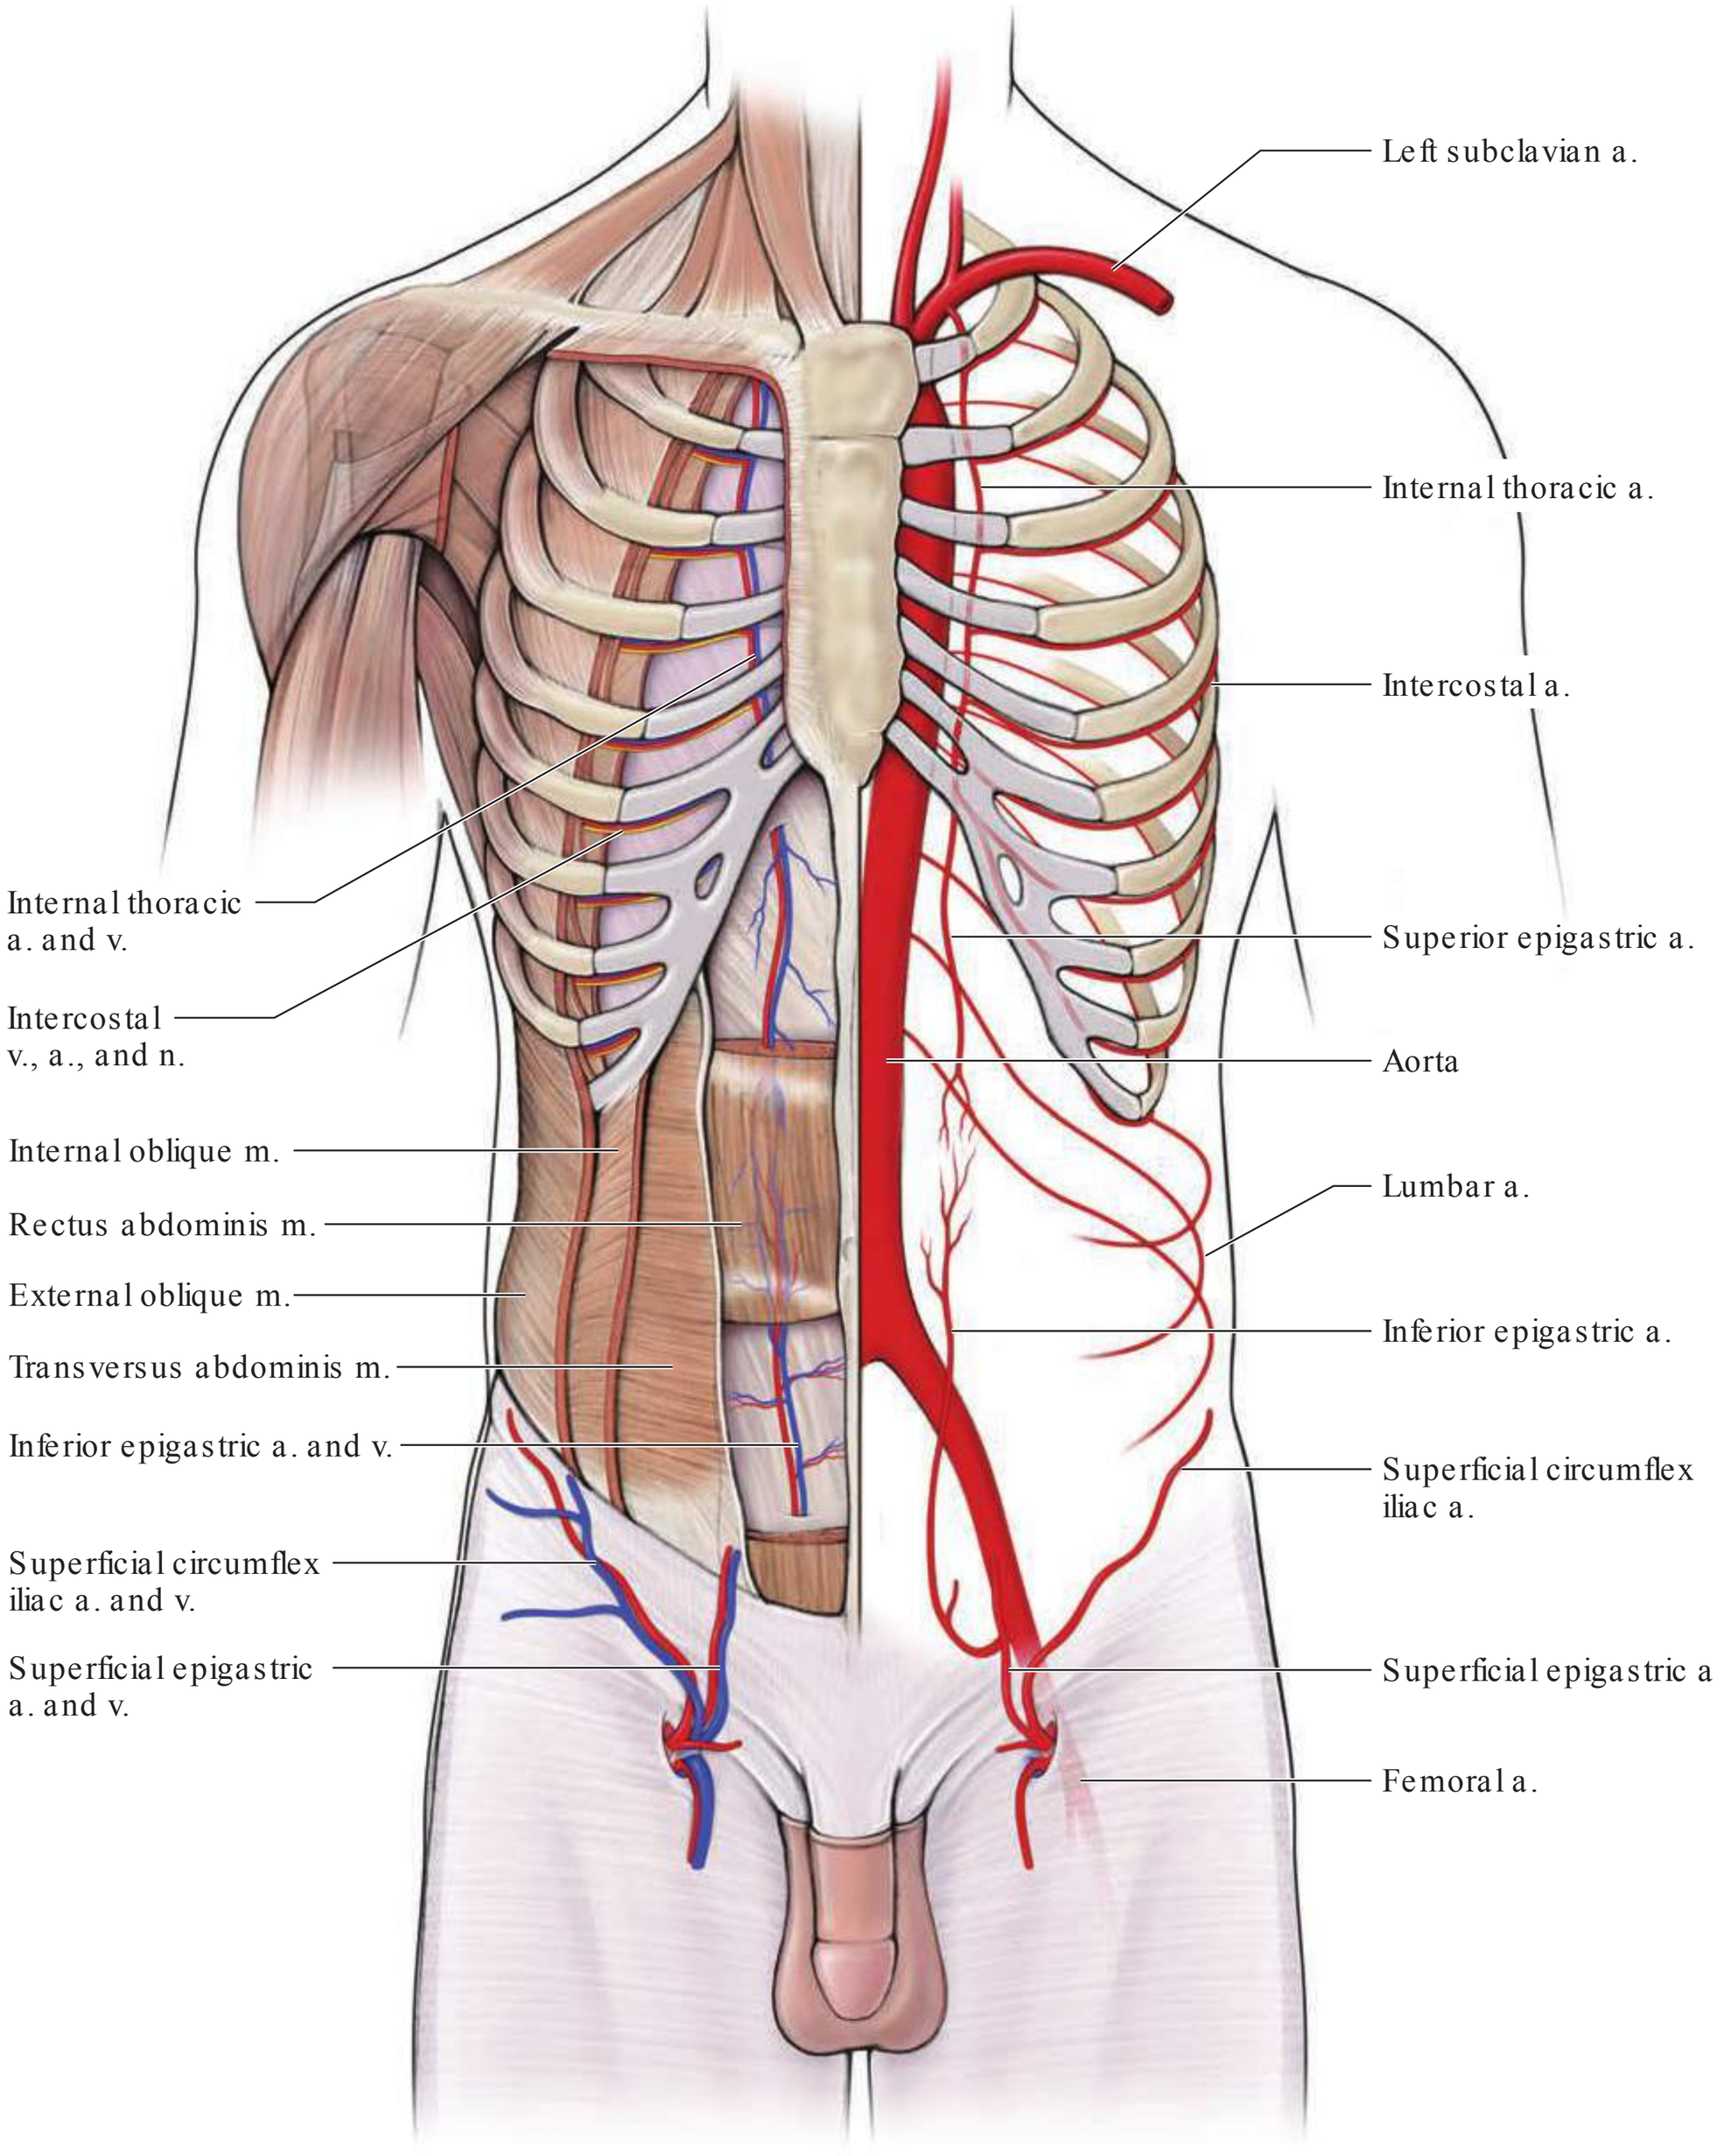

FIGURE 28-5 Vasculature of the spine. (Reproduced, with permission, from Chapter 7. Anterior Abdominal Wall. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

approximately 12 degrees in the upper lumbar spine, increasing by 1–2 degrees per segment to reach a maximum motion of 20–25 degrees between L5 and S1.[12,134]

During lumbar flexion in standing, which normally is initiated by the abdominal muscles, the entire lumbar spine leans forward, and there is a posterior sway of the pelvis as the hips flex.

CLINICAL PEARL

Flexion of the lumbar spine can also occur with a posterior pelvic tilt. The posterior pelvic tilt can be performed voluntarily, or it may occur as a result of weak paraspinal extensor muscles or adaptively shortened hamstring and gluteal muscles.[137]

At the segmental level, lumbar flexion produces a combination of an anterior roll and an anterior glide of the vertebral body, and a straightening, or minimal reversal, of the lordosis.[110,134] At L4–5, reversal may occur, but at the L5–S1 level, the joint will straighten but not reverse[138] unless there is pathology present. During the anterior rocking motion of the segment that occurs with flexion, the inferior facets of the superior vertebra lift upward and backward, opening a small gap between the facets. The superior vertebra translates anteriorly by approximately 5–7 mm, closing the gap and enhancing stability through increased tension of the joint capsule.[55] The anterior sagittal translation, or shear, is also resisted by

- the superoanterior orientation of the lateral fibers of the AF;
- the iliolumbar and SSLs at the L5–S1 segment, with the longitudinal ligaments helping to a lesser extent;
- the semisagittal and sagittal orientation of the zygapophyseal joints, which cause the superior facet to come against the inferior one during an anterior shear, with the highest pressure occurring on the anteromedial portion of the superior zygapophyseal joint surface. The zygapophyseal joints are, therefore, vital in the limitation of this anterior shear.[139]
- the horizontal vector of the erector spinae and the multifidus, which acts to pull the vertebrae posteriorly.

Flexion is also limited by the compressibility of the anterior structures, such as the IVD, and by the extensibility of the posterior structures of the segment (ligaments, IVD, and muscles). These structures have varying contributions to the resistance of segmental flexion, depending on the degree of flexion[140]:

- The joint capsule resists approximately 39%.
- The supraspinous and interspinous ligaments resist approximately 19%.
- The LF ligament resists approximately 13%.
- The IVD resists approximately 29%.

Extension

Extension movements of the lumbar spine produce a reverse of those that occur in flexion. Theoretically, true extension of the lumbar spine is pathologic and depends on one's definition: pure extension involves a posterior roll and glide of the vertebra and a posterior and inferior motion of the zygapophyseal joints, but not necessarily a change in the degree of lordosis.[134] During lumbar extension, the inferior zygapophyseal joint of the superior vertebra moves downward, impacting with the lamina below and producing a buckling of the interspinous ligament between the two spinous processes. This is impaction is accentuated when the joint is subjected to the action of the back muscles.[141] If the extending force continues to be applied, especially unilaterally, the superior facets can pivot on their inferior counterparts, producing a strain on the opposite zygapophyseal joint, and potentially damaging or tearing the capsule.[12]

CLINICAL PEARL

Repetitive contact of the spinous processes during the extremes of lumbar extension can lead to a periostitis called kissing spine or Baastrup's disease,[142] with resulting ligamentous laxity and hypermobility of the segment.[143]

An anterior pelvic tilt increases the lumbar lordosis and results in an anterior motion of the vertebrae and their associated structures. Although the differing terminology between true extension and the extension created by increasing the lordosis is seemingly esoteric, there are clinical implications during the examination, when the clinician is assessing the ability of the patient to assume the extended position of the lumbar spine.

Pure lumbar extension is limited by

- the ability of structures anterior to the fulcrum to be elongated;
- the ability of the IVD to allow compression;
- joint capsule tension; and
- the passive tension of the psoas major muscle.

AXIAL ROTATION

Intervertebral Disk

Approximately 65% of the resistance to IVD torsion is resisted by a combination of tension and impaction of the contralateral zygapophyseal joint, and tension of the supraspinous and interspinous ligaments, with the disk contributing approximately 35% of the resistance.[144] During axial rotation, which produces torsion of the IVD, those collagen fibers of the AF that are orientated in the same direction as the twist are stretched and resist the torsional force, while the others remain relaxed, thereby sharing the stress of twisting.

During forced segmental torsion, the first structure to fail is the zygapophyseal joint, which normally occurs at approximately 1–2 degrees of segmental rotation.[144] As collagen can only elongate approximately 4% before damage, the maximum segmental rotation at each segmental level is typically limited to approximately 3 degrees.[16,60] Macroscopic failure of the IVD is likely to occur only in the presence of extreme trauma, with an accompanying fracture of the zygapophyseal joint.[28] However, surgical incision of the zygapophyseal joint, or facetectomy, which increases the amount of rotation the segment is capable of handling, also significantly increases the stress in the posterior AF fibers.[28,144]

In the absence of zygapophyseal joint damage, surgical or otherwise, axial rotation must be coupled with other motions to cause disk injury.[49] For example, the combination of maximal lumbar flexion and rotation, which increases the amount of rotation before the contralateral zygapophyseal joint makes contact, has been associated with trauma to the AF.[145,146]

Other Structures

Rotational movements of the lumbar spine do appear to produce the appropriate motor patterns for optimal trunk muscle

cocontraction and spinal stability.[114,147] The axis of rotation in the sagittal plane passes through the anterior aspect of the IVD and vertebral body.[148] For axial displacements, the axis of rotation tends to be located within the posterior annulus.[148] Axial rotation of the lumbar spine amounts to approximately 13 degrees to both sides. The greatest amount of segmental rotation, approximately 5 degrees, occurs at the L5 and S1 segments. Axial rotation of the segment involves

- twisting, or torsion, of the IVD fibers;
- compression of the contralateral zygapophyseal joint, for example, with left axial rotation, the right inferior zygapophyseal joint will impact on the superior zygapophyseal joint of the bone below; and
- stress on those annular fibers inclined toward the direction of rotation.

In normal segments, the zygapophyseal joints protect the IVD from torsional injuries by coming into contact before microfailure of the IVD can occur. During axial rotation, tension is built in the interspinous and SSLs, and the contralateral joint becomes impacted after 1–2 degrees of rotation.[144] Further movement is accommodated by compression of the articular cartilage. If this range is exceeded, any further rotation that occurs is impure. Impure rotation of the segment forces the upper vertebra to pivot backward on the impacted joint, around the newly created axis of rotation. This causes the vertebra to swing laterally and backward, increasing the potential for a lateral shear force on the annulus. At this extreme, the IVD is vulnerable to either torsional or shear forces, and the other joint capsule is placed under severe tension.[28] This combination can result in a failure of any one of these structures, resulting in any or all of the following: compression fractures of the contralateral lamina, subchondral fractures, fragmentation of the articular surface and tearing, avulsion of the ipsilateral joint capsule, or a pars interarticularis fracture.[12]

The ipsilateral joint does not normally gap during normal axial rotation, except during therapeutic manipulation.[149] Abnormal gapping has been found to occur in segments with degenerative or traumatic instability, questioning the role of therapeutic manipulation in such cases.[149]

SIDE BENDING

Side bending is a complex and highly variable movement involving side bending and rotatory movements of the interbody joints and a variety of movements at the zygapophyseal joints.[136] The means of how this is achieved has been the subject of debate for many years, and it is difficult to ascertain how an impaired segment would behave, compared with a healthy one.[150] The general pattern of coupled motion is for side bending to be associated with contralateral axial rotation at the mid and upper lumbar levels but ipsilateral axial rotation at L5–S1.[136] However, there is at present little evidence for strict rules of coupled motion that determine whether an individual has abnormal ranges or directions of coupling in the lumbar spine.[136,151]

Bending motions can occur in any direction, producing both a rocking motion and a translation shearing effect on the IVD. The NP tends to be compressed and the AF buckles in the direction of the rocking motion,[152] and there is a tendency for the AF to be stretched in the opposite direction, while the pressure on the posterior aspect of the NP is relieved. Although the deformation can occur in a healthy disk, displacement of the NP is prevented by the AF that encapsulates it. The AF will buckle at its compressed aspect because it is not braced by the NP, which is exerting that effect on the AF fibers at the opposite side of the disk.[16]

AXIAL LOADING (COMPRESSION)

Axial compression or spinal loading occurs in weight bearing, whether in standing or sitting.

Intervertebral Disk

It has been demonstrated experimentally that the AF, even without the NP, can withstand the same vertical forces that an intact disk can for short periods,[153] provided that the lamellae do not buckle. However, if the compression is prolonged, or if the lamellae are not held together, the sheets buckle and the system collapses on itself.

The extent and magnitude of the compression depend on the amount of applied compressive force, the disk height, and the cross-sectional area of the disk. Variations in disk height can be divided into two categories: primary disk height variations and secondary disk height changes.

1. Primary disk height variations are related to intrinsic individual factors, such as body height, gender, age, disk level, and geographic region.[154,155]
2. Secondary disk height changes are associated with extrinsic factors, such as degeneration, abnormality, or clinical management. Surgical procedures, such as nucleotomy, diskectomy, and chemonucleolysis cause a decrease in disk height, resulting from the removal of a portion of the NP or damage to the water-binding capacity of the extracellular matrix.[156–158] In addition, there are diurnal changes in disk height, which are caused by fluid exchange and creep deformation.[159]

With variations in disk height, one would expect changes in the mechanical behavior of the disk. An important result to emerge from a recent study is that axial displacement, posterolateral disk bulge, and tensile stress in the peripheral AF fibers are a function of axial compressive force and disk height.[160] Under the same axial force, disks with a higher height-to-area ratio generate higher values of axial displacement, disk bulge, and tensile stress on the peripheral AF fibers.

The NP is deformable but relatively incompressible. Therefore, when a load is applied to it vertically, the nuclear pressure rises, absorbing and transmitting the compression forces to the vertebral end plates and the AF.[12]

- The resistance of the end plate is dependent on the strength of the bone beneath and the blood capacity of the vertebral body.
- The AF bulges radially,[161] delaying and graduating the forces.

T e peripheral pressure increases the tension on the collagen fibers, which resist it until a balance is reached, at the point when the radial pressure is matched by the collagen tension.[110]

T is equilibrium achieves two things:

1. Pressure is transferred from one end plate to another, thus relieving the load on the AF.
2. T e NP braces the AF and prevents it from buckling under the sustained axial load.

Other structures provide resistance to axial loading of the spine:

- T e ALL offers resistance if the spine is in its normal lordosis. T e lumbar lordosis while standing is approximately 50% greater than when seated.[162]
- T e inferior articular process can impact on the lamina below during strong lordosis.

During axial compression of the IVD the following occur:

1. Water is squeezed out of disk. T e water loss is 5–11%.[163]
   a. Rapid creep occurs (1.5 mm in the first 2–10 minutes)[164] and then slows (to approximately 1 mm per hour).[153]
   b. T e creep plateaus at 90 minutes.[165]
   c. Over a 16-hour day, a 10% loss in disk height occurs.
   d. A person's height is restored with unloading. T e best unloading position is in the supine knees-up posture (better than the extended supine posture).[166]
2. T e intradiskal pressure increases.

Breakdown of the System

Under normal circumstances, the NP acts like a sealed hydraulic system. Within this system, the fluid pressure rises substantially when the volume is increased (by fluid injection or by imbibing[156]) and falls when the volume is decreased (by surgical excision or axial compression loading).[158] By a similar mechanism, the age-related degenerative changes reduce the water content of the NP by 15–20%,[159] causing a 30% fall in the NP pressure.[167] In effect, the load is being transferred from the NP to the AF. T e posterior AF is affected most because it is the narrowest part of the disk and the least able to sustain large compressive strains.[160]

T e end plate is also susceptible during compression, being able to withstand only approximately one-tenth of the stress that the AF can handle.[16] Even though axial loading occurs evenly over the surface of the end plate, failure of this structure typically occurs over the NP, indicating that this central part of the end plate is weaker than the periphery.[168]

Until approximately 40 years of age, as much as 55% of the compressive load through the centrum is borne by the cancellous bone,[169] the remainder being borne by the cortical bone. After this age, horizontal trabeculae are absorbed in the center of the vertebral body, thereby weakening the part of the centrum overlying the NP. T is results in only approximately 35% of the axial stress being taken by the cancellous bone, with the greater proportion now going through cortical bone.[169] Because cortical bone fails with a smaller degree of deformation than cancellous bone, compressive failure occurs much more readily in the cortical bone.[169]

Pain originating from this failure would be expected to increase during the course of a day, especially in an individual who had spent a considerable amount of time with the lumbar spine flexed (e.g., a truck driver).[170]

CLINICAL PEARL

It is well known that during periods when the osmotic pressure within the IVD is greater than the hydrostatic pressure from axial loading (e.g., when lying in bed) the disks imbibe fluid, causing the spine to increase in length.[159,171,172] Patients should thus be advised to avoid performing full-range spinal motions (bending) shortly after rising from bed.[159,171,172]

Other Structures

Although the IVD bears most of the compressive load of the spine in the neutral position and in the very early ranges of flexion and extension, the zygapophyseal joints bear up to 25% of the compressive load in the middle ranges of extension.[173] T e contribution of the zygapophyseal joints becomes more significant during prolonged weight bearing, in the presence of IVD space narrowing, or if lumbar extension is combined with rotation.[173] In intradiskal pressure studies and electromyographic measurements of trunk muscles, in conjunction with mathematical models, investigators have estimated the compressive load on the lumbar spine to reach 1,000 N during standing and walking.[174] T e compressive load on the lumbar spine is substantially higher in many lifting activities. Large extensor moments about the joints of the lumbar vertebral column are produced by the paravertebral musculature during lifting. T ese moments result in large compressive and shear forces acting between each pair of vertebrae, as high as several thousand newtons.[175,176]

In the sagittal plane, when a compressive load is applied to a whole lumbar spine specimen along a vertical path, bending moments are induced because of the inherent curvature of the lumbar spine. As a result, the spine undergoes large changes in its curvature at relatively small load levels. Countless studies over the years have demonstrated that a neutral spine under compressive load results in bony failure,[177] specifically end-plate fracture, and damage to the underlying trabeculae,[178] and that repeated loading reduces the ultimate strength of the end plate and can cause damage to other tissues.[179,180] A burst fracture is a vertebral fracture resulting from axial impact.[181]

Distraction

A symmetric distraction of the spine is a rare force in everyday functioning, and, consequently, the disk is less resistant to distraction than it is to compression.[182] Although asymmetric distraction occurs constantly with spinal movement (side bending of the spine causes ipsilateral compression and contralateral distraction), symmetric distraction, in which all points of the one vertebral body are moved an equal distance away from its adjacent body, occurs only at times such as vertical suspension or therapeutic traction.

T e AF appears to bear the principal responsibility for restricting distraction, with the oblique orientation of the

collagen fibers becoming more vertical as the traction force is applied. For this reason, back pain reproduced with traction may implicate the AF as the source.

Shear

Shear is the movement of one vertebral body across the surface of its neighbor. T is movement can occur in any plane. Resistance to the shear forces is provided by a number of structures, including the zygapophyseal joints, the AF fibers of the IVD, and the segmental ligaments.

In forward shearing, the AF fibers on the lateral aspects of the disk predominantly resist the movement, because they lie parallel to the movement.[183] T ose angled posteriorly will be relaxed during forward shearing but tensed during backward shearing.[183] T e anterior and posterior fibers will offer some contribution to anterior and posterior shearing, but this will be much less than that of the lateral fibers.[183]

T e anterior and posterior fibers are primarily involved in lateral shearing, again with those orientated in the direction of the shear undergoing tension. As with torsion, only half of the fibers can contribute to the resistance and, as with torsion, shear forces are potentially very disruptive to the IVD.[183] It could be argued that the presence of free nerve endings in the outer part of the AF could indicate a nociceptive ability in the disk, and anything disturbing these endings may then be considered potentially painful, although there is no direct evidence to prove this.

Lumbar Stabilization

Muscle activity is available and required in the lumbar spine throughout the ROM, except in specific situations, such as at the end of lumbar flexion ROM when a reflex reduction in paraspinal muscle activity occurs, the so-called "flexion relaxation phenomenon."[120,184,185] At the end of spinal ROM, the restraints to bending, rotation and shear forces are provided largely by tension and compression on the spine's passive structures.[12] T e concept of different trunk muscles playing differing roles in the provision of dynamic stability to the spine was proposed by Bergmark,[186] and later refined by others.[78,79,114,187–189] Bergmark classified the functional role of the muscles of the lumbar spine as either mobilizers or stabilizers.[188,189] Mobilizer muscles, which tend to work over two joints or several segments, are superficial, and have narrow insertions with long tendons.[190] T e mobilizer muscles function to produce movement in the sagittal plane using concentric acceleration and are capable of generating a tremendous amount of force. T e stabilizer muscles, as their name suggests, provide stabilization. Stabilizers can be further divided into global (spanning several segments) and local stabilizers (located at a single segment).[186]

g lobal Stabilizers

T is system consists of muscles whose origins are on the pelvis and whose insertions are on the thoracic cage. T ese muscles include

- rectus abdominis;
- internal and external obliques;
- lateral fibers of the quadratus lumborum; and
- thoracic part of the lumbar iliocostalis.

T e global muscle system acts on the trunk and spine, without being directly attached to it. T ese muscles appear to provide general trunk stabilization by increasing the stiffness but are not capable of having a direct segmental influence on the spine. Cholewicki and McGill demonstrated that the quadratus lumborum was architecturally best suited to be the major stabilizer of the lumbar spine.[78] However, in general, the specific pattern of global muscle activity is task specific. Global stabilizers have a role in eccentrically decelerating momentum and controlling rotation of the spine as a whole.

Local Stabilizers

T e local muscle system consists of a series of deep muscles that have insertions or origins at the lumbar vertebrae or pelvis and are responsible for providing segmental stability and directly controlling the lumbar segments and the sacroiliac joint (see Chapter 29). T ese muscles include

- lumbar portions of the iliocostalis and longissimus thoracis muscles;
- medial fibers of the quadratus lumborum;
- lumbar multifidus;
- TrA; and
- posterior fibers of the IO that attach to the tensor fascia latae.

CLINICAL PEARL

- Transversus abdominis: the deepest abdominal muscle, may have a presetting role because it is the first trunk muscle to become active before movement initiation[115] or perturbation.[191] Together with the IO, the TrA is primarily active in providing rotational and lateral control to the spine, while maintaining adequate levels of intraabdominal pressure and imparting tension to the TLF, thereby increasing the stiffness of the lumbar spine.[192] Hodges and associates[193] found that a coactivation of the diaphragm and abdominal muscles produces a sustained increase in intraabdominal pressure. The activity of the diaphragm and TrA is initiated before rapid limb movements[194] and is tonic during repetitive movements of the arm[195,196] and walking.[197] In addition the TrA contributes to control of sacroiliac motion (see Chapter 29).
- The lumbar multifidus is considered to have the greatest potential to provide dynamic control to the motion segment, particularly in its neutral zone.[83,198] In a biomechanical study, Wilke et al. found that the lumbar multifidi are responsible for more than two-thirds of the stiffness at the L4–5 segmental level.[199]

T e local muscle system is important for the provision of segmental control to the spine and provides an important stiffening effect on the lumbar spine, thereby enhancing its dynamic stability.[99] T e local stabilizers also function to maintain a continuous low-force activity at joints in all positions and directions and thus provide segmental joint support.

CLINICAL PEARL

The lumbar multifidus, transversus abdominis TrA, and the posterior fibers of the IO are known to be tonically active during upright postures and active motions of the trunk,[200] with the transversus abdominis capable of tonic activity irrespective of trunk position, direction of movement, or loading of the spine.[192]

Two prominent and similar theories for active lumbar stabilization are the bracing mechanism, proposed by McGill,[201] and the deep corset mechanism, proposed by Richardson et al.[114]

- Bracing mechanism: muscles act similar to guy wires when stabilizing the spine and that a loss of tension can result in unstable buckling of the spinal structures. T e muscles of the trunk function via a complex interaction of agonist/antagonist spinal muscles, both segmentally and regionally to provide tension (active stiffness). According to this theory lightly pretensioning, or bracing, the abdominal muscles using an isometric contraction is a way to enhance the guy wire affect by taking up the slack prior to activities that may destabilize the spine.[202] T e external oblique, IO, and TrA overlay each other to create the abdominal wall and act through attachments to the abdominal and TLF to create a cylinder. As the intraabdominal pressure increases, the three-dimensional force per unit area exerted on the spine also increases, potentially constraining spinal movement in all directions.
- Deep corset mechanism: Richardson et al.[114]have proposed that a pressure corset is formed by the muscles of the lumbar spine. Under this proposal, the TrA forms the wall of the cylinder, and the muscles of the pelvic floor and diaphragm form the base and lid, respectively. Within this system, the intraabdominal pressure group is maintained at a level that provides spinal support.[95,114,193,203] Since the abdominal cavity has a finite volume, the intraabdominal pressure (force/area) will increase if the abdominal cavity volume is reduced (contraction of the muscles in the pelvic floor, abdominal muscles and diaphragm, and the wearing of a lumbar corset). In addition, the increase in intraabdominal pressure is thought to provide a mild distractive force to the spinal segments, due to separation of the pelvic floor and diaphragm. Because intraabdominal pressure and fascial tension are important for the control of intervertebral motion, the muscles that surround the abdominal cavity, such as the diaphragm and the pelvic floor muscles (see Chapter 29), provide an additional contribution. T ese two muscle groups also have important respiratory and continence functions. T eoretically, reduced contribution of the diaphragm to spinal stability may occur during periods of increased respiratory demand. As the diaphragm descends during inspiration, intraabdominal pressure increases provided that the musculature of the abdominal and pelvic floor maintains its respective tension. Conflicting evidence exists on what strategy is the most effective in preventing back injury during lifting. Although lifting from a squat position, using the legs, with the lumbar spine maintained in lordosis is a commonly taught strategy, there is little evidence to support that this posture reduces compressive and shear forces acting on the spinal segments.[204] Existing evidence suggests that compressive and shear forces acting on the lumbar spine are most influenced by load moment, lifting speed, and acceleration.[205] A study by Kigma et al.[204] showed that the width of an object and the height from which an object is lifted are more important determinants of forces acting on the lumbar spine than the strategy used to perform the lift. T e study further suggests that squatting may be an effective technique to reduce compressive forces acting at L5–S1 when lifting narrow loads, such as those loads that can be placed between the feet, but straddling and stooping techniques are more effective at reducing compressive forces when lifting wider loads from the floor[204] Although current training programs for lifting focus on maintaining the load's proximity to the body's center of gravity (COG), minimizing trunk rotation, matching the load magnitude to the lifter's capacity, and avoiding fatigue, it remains unclear the role that breath control may play in achieving lumbar segmental control during lifting tasks.[206] An intriguing study by Hagins and Lamberg[206] reported that individuals with LBP performed a lifting task with more inhaled lung volume than individuals without LBP.

CLINICAL PEARL

Cholewicki and McGill[78] reported that lumbar stability is maintained in vivo by increasing the activity (stiffness) of the lumbar segmental muscles, and they highlighted the importance of motor control to coordinate muscle recruitment between large trunk muscles and small intrinsic muscles during functional activities, to ensure stability is maintained. These muscle activations are not restricted to the motion of the spine. For example, studies of arm movement suggest that when the limb is moved, the nervous system does not simply stiffen the trunk; rather, the spine and pelvis move in the direction opposite to the perturbation.[207]

Lumbar instability is considered to be a significant factor in patients with chronic LBP.[208] Because of the close relationship between the passive anatomical restraints of the lumbar spine and the muscles that control it, it would seem logical to assume that any pain-provoking injury, or any condition that alters the structural integrity of the lumbopelvic complex (muscle strain, ligament sprain, disk herniation, etc.) is by definition a "clinical instability." Growing evidence is emerging to support this hypothesis.[209–211] Various studies have demonstrated that coordinated patterns of muscle recruitment are essential between the global and local system muscles of the trunk to compensate for the changing demands of daily life and to ensure that the dynamic stability of the spine is preserved.[78,185,212,213] In normal subjects with no history of LBP, the TrA, erector spinae, and obliquus internus abdominis are recruited just prior to any limb movement.[214] Several studies indicate that the deep abdominal muscles undergo changes in

their functional performance in populations with LBP.[79,214,215] These studies have shown that it is the local system that is particularly vulnerable to breakdown. In particular, the prevalence of LBP is being attributed to inhibition and atrophy of the multifidi and TrA, and the resultant poor neutral zone stabilization, although the reasons as to why these two muscles become inhibited and atrophied is unclear.[79,116,212,216,217] Cholewicki and McGill[78] reported that the lumbar spine is more vulnerable to instability in its neutral positions, at low load and when the muscle forces are low. They confirmed that under these conditions, lumber stability is maintained in vivo by increasing the activity (stiffness) of the lumbar segmental muscles (local muscle system). Furthermore, they highlighted the importance of motor control to coordinate muscle recruitment between large trunk muscles (the global muscle system) and small intrinsic muscles (the local muscle system) during functional activities to ensure that mechanical stability is maintained.[185]

The scientific literature reports varying disruptions in patterns of recruitment and cocontraction within and between different muscle synergies.[185] Studies also have described subtle changes or shifts in the pattern of abdominal muscle activation and righting responses in subjects with chronic LBP.[82,218] These changes in the activation patterns result in altered patterns of synergistic control or coordination of the trunk muscles.[215,219] In addition to pain, generalized changes to the trunk musculature, such as a loss of strength, endurance, and muscle atrophy are also believed to produce changes in the neural control system, affecting the timing of patterns of cocontraction.

CLINICAL PEARL

It is important to note that reports on the changes that occur in the control of trunk muscles in the presence of LBP vary considerably with an increase,[220] a decrease,[221] and no change[222] being reported. What is clear is that enormous variability is seen in the adaptation of the trunk muscles in people with lumbopelvic pain.

EXAMINATION

Given the numerous causes and types of LBP, it is imperative that any clinician examining and treating the lower back have a sound understanding and knowledge of the anatomy and biomechanics of this region. Although this knowledge is not the sole determinant of the approach to LBP, it does provide a solid framework on which to build successful management. There have also been moves toward the design of clinical prediction rules (see Chapter 5) on how best to treat patients with LBP (see "Intervention" section).

LBP can arise from a number of local structures in the lumbar spine and a number of sources more distal (see Chapter 5). A number of local structures have been found to cause LBP when stimulated. Theoretically any innervated structure in this area can cause symptoms so the distributions and descriptions of referred symptoms must always be considered in relation to the neurologic supply of the lumbar segment. For example, McCullogh and Waddell[223] studied the effects of electrical stimulation of spinal ligaments, muscles, the AF, and the NP and found that these structures referred pain to the buttock and upper leg, but rarely below the upper calf. The reported pain was dull and poorly localized. In contrast, stimulation of the nerve roots produced a sharper, more localized pain, often with some paresthesia. Stimulation of the L5 and S1 nerve roots nearly always radiated to or below the ankle.

Idiopathic and nonspecific LBP have emerged as catchall terms in the diagnosis of low-back dysfunction. Indeed, up to 85% of patients cannot be given a definitive diagnosis because of weak associations among symptoms, pathologic changes, and imaging results.[33,224] Muscle aches, muscle sprains, tendinitis, sacroiliac and low-back strain, lumbago, mechanical LBP, and lumbar strain are just some of the diagnoses currently in clinical use. This is difficulty in determining a specific diagnosis stems from a variety of reasons, including the fact that multiple structures in one or more segments may be involved. These structures include the interconnecting ligaments, the outer fibers of the annulus fibrosus, zygapophyseal joints, vertebral periosteum, paravertebral musculature and fascia, blood vessels, and spinal nerve roots.[224]

A number of associated occupational, psychosocial, and environmental factors can be used to help predict the development of a complicated course of LBP.[225–231] These include the following:

- **Genetics.** A number of studies[232–234] have suggested that genetic factors play an important role in the development of lumbar disk degeneration, but their role in the cause of clinical LBP is unclear.
- **Age older than 40 or 50 years.** The relation between chronic LBP and age over 40 or 50 years, with a decrease of occurrence over 60 years, is considered as an established fact in many reviews.[235,236] The link between spinal degeneration and chronic LBP often has been assumed, because the severity of the radiographic abnormalities makes it logical to infer a cause-and-effect correlation.[237–239] Conditions such as osteoarthrosis, congenital anomalies, and postural misalignments have often been assumed to relate to LBP, but the evidence to support these assumptions (with the exception of some degenerative changes) has been inconclusive.[238–240] Indeed, given the low correlation of radiographic findings and clinical signs and symptoms, some physicians feel that radiographs are not necessary initially in the workup of acute nontraumatic LBP.[238]
- **Low level of formal education and social class.** For back pain, specifically, some studies have found an inverse relation of formal education, social class, or both to the prevalence of back pain symptoms.[240–242] A tentative conclusion, although not based on an extensive literature review, indicates that lower levels of socioeconomic status and education are better predictors of adverse prognosis for occupational disability from back pain than are risk factors per se.[243]
- **Physical workload.** From a number of studies that examined the relation between physical and psychosocial load at work and the occurrence of LBP, it has been concluded that both work-related physical factors of

flexion and rotation of the trunk and lifting at work, and low job satisfaction, are risk factors for sickness absence resulting from LBP.[244,245] Physical load on the back has commonly been implicated as a risk factor for LBP and, in particular, for work-related LBP. Certain occupations and certain work tasks seem to have a higher risk of LBP.[246–249] Repeated lifting of heavy loads is considered a risk factor for LBP,[27] especially if combined with side bending and twisting.[250,251] A study of static work postures found that there was an increased risk of LBP if the work involved a predominance of sitting.[252] Kelsey[253] and Kelsey and Hardy[170] found that men who spend more than half their workday driving have a threefold increased risk of disk herniation. A growing body of evidence indicates that exposure to vibration and jolting in workers who operate tractors, excavators, bulldozers, forklift trucks, armored vehicles, lorries, helicopters, and many other vehicles and machines may cause an increased risk of LBP.[253–257]

- Sciatic pain. LBP radiating to a leg (i.e., sciatic pain) seems to be a more persistent and severe type of pain than nonspecific LBP. Sciatic pain also causes more disability and longer absence from work.[34] In patients with sciatic pain (sciatica) from disk herniation, radiographic examinations such as myelograms, computed tomographic (CT) scans, and MRI scans demonstrate nerve root compression by a herniated disk. However, sciatica can have a number of causes (Table 28-2).

CLINICAL PEARL

Approximately 20–30% of individuals without any history of sciatic pain have abnormal findings in radiographic examinations.[258]

- Smoking. In some epidemiologic studies, smoking has been associated with LBP.[259,260] Several possible pathophysiologic mechanisms have been proposed to explain the association. It has been suggested that smoking accelerates degeneration by impairing the blood supply to the vertebral body and nutrition of the IVD.[261] Smoking also increases coughing activity, which causes an increase in intradiskal pressure.[262] Also, it has been hypothesized that the high serum proteolytic activity in the blood of cigarette smokers gains access to a previously degenerated neovascularized disk and accelerates the degenerative process. Increased proteolytic activity may also weaken the spinal ligaments, resulting in spinal instability.[263] However, besides its direct harmful effects, and its link to other health risk factors as well as lifestyle and behavioral patterns, no substantive evidence appears to support smoking as a definitive cause of LBP.[259]

- Obesity. There are several hypotheses relating to a link between obesity and LBP. Increased mechanical demands resulting from obesity have been suspected of causing LBP through excessive wear and tear,[154,155,264,265] and it has been suggested that metabolic factors associated with obesity may be detrimental.[264] An interesting study by Fransen et al.[266] reported that although obesity does not appear to be causative, it may have a meaningful impact on how long LBP persists.
- Psychological factors. It has been established that people who are simultaneously subjected to demanding physical and psychosocial conditions have more LBP than people with only demanding physical or only demanding psychosocial conditions.[267] Four explanations for the association between psychosocial work characteristics and musculoskeletal symptoms have been suggested[268]: (1) psychosocial work characteristics can directly influence the biomechanical load through changes in posture, movement, and exerted forces; (2) these factors may trigger physiologic mechanisms, such as increased muscle tension or increased hormonal excretion, that may, in the long term, lead to organic changes and the development or intensification of musculoskeletal symptoms or may influence pain perception and thus increase symptoms; (3) psychosocial factors may change the ability of an individual to cope with an illness, which, in turn, could influence the reporting of musculoskeletal symptoms; and (4) the association may well be confounded by the effect of physical factors at work. It seems plausible that psychosocial factors in private life also could affect musculoskeletal symptoms through the second and the third mechanism.[268] Studies have also found an effect of low workplace-social support and low job satisfaction. However, the effect found for low job satisfaction may be a result of insufficient adjustment for psychosocial work characteristics and physical load at work.[268] Although psychological factors, like obesity, appear to have a meaningful effect on the duration of LBP, they do not cause LBP.
- Comorbidity. Comorbidity may slow or interfere with normal recovery from back pain and may affect an individual's general sense of health, leading to a decreased self-perception of capability.[269]

A recent report issued by the Agency for Health Care Policy and Research,[270] now known as the Agency for Healthcare Research and Quality, suggests grouping back pain into five broad categories[271]:

- potentially serious spinal conditions, such as a spinal tumor, infection, fracture, and cauda equina syndrome.

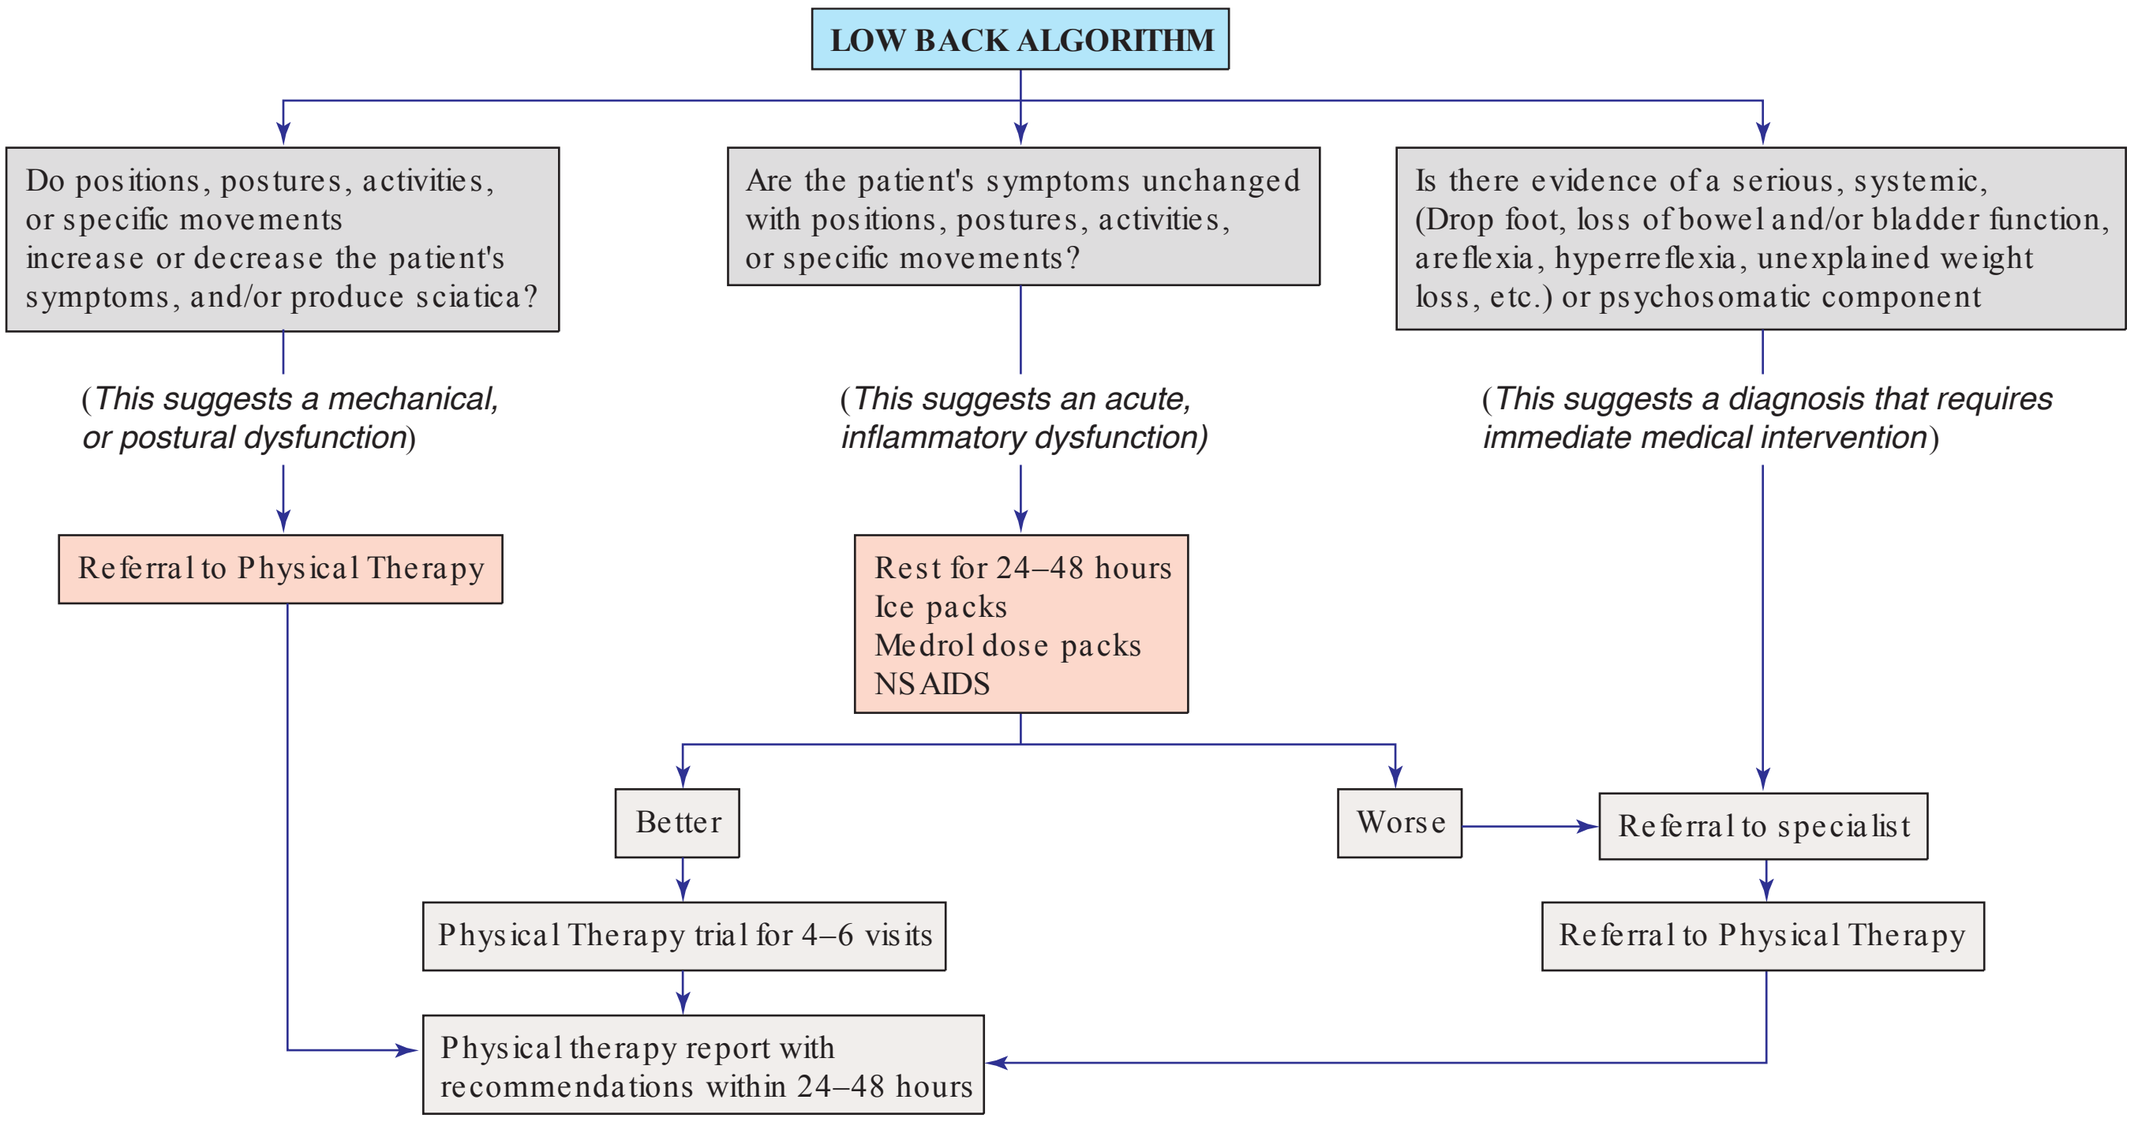

FIGURE 28-6 Examination algorithm for the low back.

Although the likelihood of a low-back syndrome due to a serious condition is low, the consequences of a missed diagnosis or delayed treatment can be quite costly in terms of prolonged morbidity and, in the extreme, mortality.[271]

- nonspinal causes secondary to abdominal involvement (gallbladder, liver, renal, pelvic inflammatory disease, prostatic carcinoma, ovarian cyst, uterine fibroids, aortic aneurysm, or thoracic disease);
- sciatica and dural tissue compromise;
- nonspecific back symptoms, the majority of which are mechanical in nature;
- psychological causes such as stress and work environment (disability, workers' compensation, and secondary gain).

CLINICAL PEARL

The physical examination of the lumbar spine must include a thorough assessment of the neuromuscular, vascular, and orthopaedic systems of the hip, lower extremities, low-back, and pelvic region.[272] Figure 28-6 depicts a simple algorithm for decision making during the examination of the lumbar spine.

History

The clinician should establish the chief complaint of the patient, in addition to the location, behavior, irritability, and severity of the symptoms. Although dysfunctions of the lumbar spine are very difficult to diagnose, the history can provide some very important clues (Table 28-3). Applying the principles and rationale outlined in Chapters 4 and 5, the clinician uses the history to help with differential diagnosis. A useful organizational acronym for this purpose is LOP4QRST, which represents the following descriptors[271]:

- location;
- onset;
- prior history/treatment;
- palliative measures (including medications);
- provocative factors (including movement/positional factors);
- progression/course;
- the quality of symptoms;
- referral patterns;
- severity; and
- temporal factors.

A lower-back medical screening questionnaire is provided in Table 28-4.

- Location. Back pain may be localized centrally, unilaterally, or bilaterally. Differential diagnosis should include certain gastrointestinal conditions such as inflammatory bowel disease, appendicitis, or cholelithiasis. Generally speaking, the stronger the pain stimulus, the larger the area of pain reference will be. As the stimulus intensity decreases, the referred pain area becomes smaller, and localization of the pain by the patient becomes easier for the patient. The distribution of the pain should be described by the patient and outlined on a pain diagram. Central back pain is unlikely to be caused by a unilateral structure, such as a zygapophyseal joint or the sacroiliac joint, and bilateral pain hardly ever has a central origin (one of the exceptions being a central IVD protrusion).[273]

TABLE 28-3 Reliability of the Historical Examination[a]

Historical Question	Population	Kappa Value or % Agreement
Patient report of (McCombe et al.)[b]	Group 1:50 patients with low-back pain	Interexaminer reliability
Foot pain		$\kappa = 0.12, 0.73$
Leg pain		$\kappa = 0.53, 0.96$
Thigh pain	Group 2:33 patients with low-back pain	$\kappa = 0.39, 0.78$
Buttock pain		$\kappa = 0.34, 0.44$
Back pain		$\kappa = 0.19, 0.16$
Pain ever below the knee	475 patients with back pain	Test–retest among patient questionnaire
		Agreement 100%
Pain ever into the foot		Agreement 92%
Numbness below knee (Waddell et al.)[c]		Agreement 95%
Increased pain with (Roach et al.)[d]	53 subjects with a primary complaint of low-back pain	Test–retest among patient questionnaire
Sitting		$\kappa = 0.46$
Standing		$\kappa = 0.70$
Walking		$\kappa = 0.67$
Increased pain with (Vroomen et al.)[e]	A random selection of 91 patients with low-back pain	Interexaminer reliability
Sitting		$\kappa = 0.49$
Standing		$\kappa = 1.0$
Walking		$\kappa = 0.56$
Lying down		$\kappa = 0.41$
Pain with sitting (Van Dillen et al.)[f]	95 patients with low-back pain	Interexaminer reliability
		$\kappa = 0.99, 1.0$
Pain with bending (Van Dillen et al.)[f]		Interexaminer reliability
		$\kappa = 0.98, 0.99$
Pain with bending (Roach et al.)[d]	53 subjects with a primary complaint of low-back pain	Test–retest among patient questionnaire
		$\kappa = 0.65$
Pain with bending (McCombe et al.)[b]	Group 1: 50 patients with low-back pain	Interexaminer reliability
	Group 2: 33 patients with low-back pain	$\kappa = 0.51, 0.56$
Increased pain with coughing/sneezing (Vroomen et al.)[e]	A random selection of 91 patients with low-back pain	Interexaminer reliability
		$\kappa = 0.64$
Increased pain with coughing (Roach et al.)[d]	53 subjects with a primary complaint of low-back pain	Test–retest among patient questionnaire
		$\kappa = 0.75$
Pain with pushing/lifting/carrying (Roach et al.)[d]		Test–retest among patient questionnaire
		$\kappa = 0.77, 0.89$
Sudden or gradual onset of pain[c]	475 patients with back pain	Test–retest among patient questionnaire
		Agreement = 79%

- An inflammation of the zygapophyseal joints can cause local back pain or buttock pain,[274] but it also has been associated with pain referred to the buttocks and even below the knee.[132,223,275]

CLINICAL PEARL

Various research studies have been undertaken to establish the validity of history taking for use in diagnosing a

lumbar disk herniation.[224,276–278] Deyo et al.[224] reported a sensitivity for sciatic distribution of pain in the diagnosis of lumbar disk herniation of 95%, and calculated that the likelihood of a disk herniation being present in the absence of sciatic pain as 0.1%. Similarly, high degrees of sensitivity have been found in other studies.[276–278] Radiculopathy is such a sensitive finding (95%) that its absence almost rules out a clinically important disk herniation, although it is only 88% specific for herniation.[279] In contrast, the sensitivity of pseudoclaudication in detecting spinal stenosis is 60%, whereas the combination of pseudoclaudication and age greater than 50 years has a sensitivity of 90% (specificity, 70%).[279] One study[280] showed that taking the history and MRI findings into account, elderly patients with protruded herniation were considered to be more likely to experience groin pain, with the rate of L4–5 disk involvement being higher than that of L5–S1 involvement. These results support conclusions drawn from a study by Murphey,[281] which found that groin and testicular pain are rare with L5–S1 disk disease but are fairly common with L4–5 disk disease.

TABLE 28-4 Medical Screening Questionnaire for the Low-Back Region

	Yes	No
Have you recently had a major trauma, such as a vehicle accident or a fall from a height?		
Have you ever had a medical practitioner tell you that you have osteoporosis?		
Do you have a history of cancer?		
Do you have pain at night that wakes you up?		
Does your pain ease when you rest in a comfortable position?		
Have you recently had a fever?		
Have you recently lost weight even though you have not been attempting to eat less or exercise more?		
Have you recently taken antibiotics or other medications for an infection?		
Have you been diagnosed as having an immunosuppressive disorder?		
Have you noticed a recent onset of difficulty with retaining your urine?		
Have you noticed a recent need to urinate more frequently?		
Have you noticed a recent onset of numbness in the area where you would sit on a bicycle seat?		
Have you recently noticed your legs becoming weak while walking or climbing stairs?

- Groin pain, although also associated with hip pathology and other conditions, is a complaint often present in patients with a high lumbar IVD herniation.[280] On questioning, patients with this form of groin pain often describe the pain as a dull ache lying deep beneath the skin, which they usually find difficult to localize with any degree of accuracy. Although the patient with a high lumbar IVD herniation often reports pain and numbness on physical examination, the clinician is often unable to discern any specific findings, such as tenderness, muscle weakness, or hypesthesia, except perhaps occasionally a slight hyperalgesia.[280]
- Leg pain reported by the patient may indicate a radiculopathy or a pseudoradiculopathy. Conditions that may result in radicular symptoms include inflammatory irritation due to tissue injury, disk herniation, and subsequent nerve root irritation. In general, with a disk protrusion, the presence of leg pain indicates a larger protrusion than does back pain alone.[282] Coughing, sneezing, or a Valsalva maneuver typically exacerbates the symptoms. Other conditions capable of producing radicular-like symptoms include arthrosis involving the facet joints or vertebral body–disk interface, spinal hematoma, and congenital or acquired central or lateral canal stenosis.[271] A pseudoradiculopathy, as its name suggests, is pain that is radicular in distribution but is caused by something other than those conditions mentioned. Examples of a pseudoradiculopathy include referred pain and symptoms produced by a facilitated segment.[283] Despite the obvious differences in pathology, pseudoradiculopathy and radiculopathy have the common elements of dermatomal pain, diminished reflexes, muscle weakness, and positive nerve provocation tests.[132,283,284] Distinguishing between the two is, therefore, difficult. In general, unilateral pain with no referral below the knee may be caused by the lumbosacral structures other than the spinal nerves, whereas irritation of a spinal nerve may cause radicular symptoms below the knee.[285] On occasion, the patient may report feeling back pain more than leg pain or vice versa. Patients who report a dominance of leg pain over back pain and whose symptoms are worsened by flexion of the lumbar spine most likely have nerve root irritation caused by an IVD herniation.[285] The clinician should also ask the patient about any difficulty with coughing, sneezing, or abdominal straining (Dejerine's triad), each of which causes an increase in intrathecal pressure that may provoke radicular symptoms.[271] Patients with bilateral root pain should be suspected of having a central disk protrusion, spondylolisthesis, bilateral stenosis of the lateral spinal recesses, a narrowed spinal canal, or malignant disease.[286]
- Onset. When did the problem begin, how long has the patient had the problem, and have similar episodes occurred in the past? Low-back disorders may be acute, chronic, or recurrent. If possible, the clinician should attempt to order the onset of symptoms chronologically and then determine what has occurred to the symptoms since the onset. The mechanism of injury for the lumbar spine usually involves lifting, bending, or twisting, or a

TABLE 28-5	Intradiskal Pressures and Forces Generated by Common Tasks
Task	**Total Load (kg)[a]**
Lying supine	25

Lumbar intradiscal pressure. In: Jayson MIV, ed. The Lumbar Spine and Back Pain. Edinburgh: Churchill Livingstone; 1987:191–203.

combination of all three.[253] However, postural ligamentous pain tends to be more frequent in patients who stand or sit for long periods at work.[287] If an obvious cause is reported, the clinician should confirm the direction, amount, and duration of any forces involved. The forces applied to the lumbar spine and IVD vary according to the task or position of the body (Table 28-5). In general, a sudden onset of pain associated with an activity or movement suggests a ligament, muscle, or IVD as the source, whereas a gradual onset of symptoms suggests a degenerative process or a lesion that is increasing in size, such as a neuroma or neoplasm.[286] While pain is suggestive of mechanical or chemical irritation, paresthesia, anesthesia, and weakness are attributed to decreased nerve or arterial function due to compression, constriction, or other blockage.[271] If the onset of symptoms in a female patient is cyclical in nature, the clinician should consider certain gynecologic conditions, including endometriosis, pelvic inflammatory disease, and pregnancy.

The frequency of the episodes often can give the clinician an indication of severity. Stable episodes of symptoms (e.g., symptoms that only occur every few years and do not change much in severity with each episode) are generally easier to treat than episodes that occur daily or weekly and appear to be worsening.

- Prior history/intervention. Patients should be asked if they have experienced similar complaints or problems in the past, even if the current complaint feels different. If so, it is helpful to determine what intervention was provided, whether self-administered or by a health-care provider, over what length of time and if that treatment was effective.[271] Prognostic factors for the development of recurrent LBP include the history of previous episodes, excessive spinal mobility, and excessive mobility in other joints.[11] Prognostic factors for the development of chronic pain include the presence of symptoms below the knee, psychological distress or depression, fear of pain, movement, and reinjury or low expectations of recovery, pain of high intensity, and a passive coping style.[11]

- Palliative measures. It is important to determine what attempts have been made to alleviate the symptoms and what effect, if any, was achieved. Depending on the nature of the pathology, certain body positions may bring relief, although it is important to remember that patients often present with symptoms more complex than classic textbook examples allow[271]:
- Lying supine with knees flexed decreases pressure on the spinal column and tension of neural elements. Similar relief may be felt in the side-lying position; however, patients with a neurocompressive disk herniation may find this position unsustainable on one side and tolerable on the other side.
- Standing or extension may be less provoking than seated or flexed positions in patients with disk pathology, whereas the opposite is typically true of patients with spinal stenosis. A classic example of positional relief involves the stenotic patient who leans on a shopping cart while walking to alleviate back and lower extremity symptoms.

Pathology of nonmechanical origin is usually nonresponsive to provocative movement and may be negatively responsive to positional changes, as in the case of sepsis within the abdominal cavity and neoplastic activity.[271,288]

- Provocative *f*actors (Table 28-6). Information about the activities or positions that aggravate or relieve the symptoms provides the clinician with an insight as to whether the patient has a mechanically related disorder or one that is nonmechanical. In general, musculoskeletal pain is reduced with rest although it is worth remembering that in postural syndromes, the symptoms are usually increased by the maintenance of a particular posture and relieved by altering the position. For example, if the patient complains of pain with standing with the feet together, the cause of the pain could be stresses on the structures caused by an increased lordosis, especially if the pain is reduced by placing one foot in front of the other, or if the pain is reduced when the lumbar lordosis is reduced with an active posterior pelvic tilt. Pain that is relieved by sitting and forward bending but aggravated by walking may indicate a zygapophyseal joint problem, spondylolisthesis (in the younger patient), or lateral recess or spinal stenosis (in the elderly patient). Pain that is aggravated by sitting, stooping, or lifting, but is relieved by recumbency and is not increased by brief periods of

TABLE 28-6	Relieving Positions or Movements
Relieving Position or Movement	**Probable Cause**
Flexion	Facet joint involvement Low-back strain Lateral stenosis
Extension	Disk involvement Nerve root irritation (disk herniation)
Rest	Neurogenic claudication

standing and walking may indicate an IVD lesion such as a protrusion or an annular tear.[289] In addition to those patients with an IVD protrusion, pain with coughing and sneezing also occur in patients with active sacroiliitis, because the sudden increase in intraabdominal pressure produces a painful distraction of the sacroiliac joints.[273] Once the motion or position that reduces the symptoms is identified, the initial focus of the intervention is teaching the patient strategies that encourage this motion or posture.

- Progression and course of symptoms. Questions related to the type and behavior of symptoms can help determine the structure involved and the stage of healing. It is important to determine whether the condition is improving or worsening. Constant pain indicates an inflammatory process. Steadily increasing pain, especially in elderly patients, may indicate malignancy.[286] Pain that is gradually expanding and increasing is associated with a lesion that is increasing in size, such as a neuroma or neoplasm.[286] Pain with movement suggests a mechanical cause of pain. If the muscles and ligaments are involved, activity will tend to decrease the pain, but the pain will worsen with repeated movements or sustained positions as the structures become fatigued or overstressed.[282,290] Dural pain tends to be diffuse, vague, and spreads upward to the chest or downward to the thighs.[273]

Symptoms of lumbosacral pathology can demonstrate a phenomenon of centralization and peripheralization.[282,291,292] Centralization of symptoms is the progressive retreat of the most distal extent of referred or radicular pain toward the lumbar spine midline in response to standardized movement testing during evaluation of the effect of repeated movements on pain location and intensity. Peripheralization of symptoms indicates movement in the opposite direction. Centralization of the symptoms normally indicates improvement in the patient's diskogenic condition (see "Special Tests" section).[293]

- The quality of symptoms. Pain is the most common initial complaint involving the low back. Descriptors used by the patient to characterize his or her pain can provide valuable clues to the origin of the problem (Table 28-7).
- Radiation/referral of symptoms. LBP that emanates from the bony structures, soft tissues, or neural elements often demonstrates an associated pattern of referral or radiation.[271] At a given spinal level, the similar pain patterns of dermatomal, myotomal, and sclerotomal pain represent the distributions of a single nerve root. However, based on the pattern alone, it is difficult to determine the offending structure involved.[271] Radicular and dermatomal pain are often used interchangeably although their meanings are distinct:
  - Radicular pain refers to pain initiated by nerve root irritation and presents itself along the pathway of the root.
  - Dermatomal pain is defined as pain within the distribution of a single sensory nerve root that innervates the skin and presents itself at the surface.

Two additional definitions are pertinent. A myotome consists of groups of muscles supplied by a single spinal segment, whereas a sclerotome is an area of bone or fascia supplied by a single spinal segment.[271]

- Severity. The most frequently used tool to assess severity is a numerical rating scale, with 0 representing the absence of pain and either 10 or 100 representing the most extreme intensity of pain that the patient has experienced or can imagine. There are several other tools that provide quantification of the patient's symptoms to greater or lesser degree[271]:
  - The visual analog scale is frequently used, particularly with new patients and during reexaminations. The scale consists of a 10-cm unmarked line, with indicators of "no pain" at the left end of the line and "extreme pain" at the right end of the line. Patients are asked to mark the line at the point corresponding to their pain level.
  - Color charts are useful for young patients and patients who have difficulty communicating information due to language barriers. The colors extend from red to violet, with red representing extreme pain and violet representing the absence of pain.
  - Verbal descriptors, such as minimal, slight, moderate, and severe, may also be used to categorize pain levels, although can be subject to misinterpretation. It is important to quantify a patient's pain intensity at its current level, when it is at its lowest and highest points, and an average estimate over a selected period of time, for example, 1 week.[271] This information may then be used as outcome measures for subsequent treatment.
- Temporal factors—diurnal or nocturnal variation in symptoms. Determining the connection between the time of day and onset of symptoms may help differentiate between mechanical and inflammatory disorders. For example, muscle strains may feel slightly sore in the morning on waking but typically result in a greater intensity of pain at the end of the day following activity.[271] A patient with an inflammatory condition such as ankylosing spondylitis, an IVD lesion, osteoarthritis, ankylosing spondylitis, or Scheuermann's disease tends to experience the greatest symptoms in the morning, after the joints and surrounding tissues have had ample time to stiffen. In addition, patients with mechanically based pain often report an increase in symptoms during the evening hours, when their attention is not diverted by work or daily activities.[271] This may also be true when looking at pain patterns during the week when much activity occurs

TABLE 28-7 Common Descriptors of Pain and Their Origin

Descriptor	Origin
Deep ache, and boring	Bony tissues
Dull, achy, sore, burning, and cramping	Muscle/fascia
Sharp, knife like, shooting, lancinating, tingling, burning, numbness, and weakness	Nerve
Burning, stabbing, throbbing, tingling, and cold	Vascular
Deep pain, cramping, and stabbing	Visceral

TABLE 28-8 Red Flags for the Low-Back Region

Condition	Red Flags
Back-related tumor	Age over 50 yr History of cancer Unexplained weight loss Failure of conservative therapy
Back-related infection (spinal osteomyelitis)	Recent infection (e.g., urinary tract or skin infection) Intravenous drug user/abuser Concurrent immunosuppressive disorder
Cauda equina syndrome	Urine retention or incontinence Fecal incontinence Saddle anesthesia Global or progressive weakness in the lower extremities

Sensory deficits in the feet (i.e., L4, L5, and S1 areas).

Data from DuVall RE, Godges J. Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1. La Crosse, WI: Orthopaedic Section, APTA, Inc.; 2003:1–44.

at home and work versus during the weekends when rest is more likely.[271] Night pain that wakes a patient may be an indicator of neoplastic activity or infection ("Red Flags") (Table 28-8) and should be addressed immediately. In contrast, a patient who awakens following movement, such as changing positions while sleeping, would be less of a risk for "Red Flags."[271] The same is true of the patient who has difficulty returning to sleep after getting up, for example, to visit the restroom.[271] Depending on the size of the patient, prone lying tends to compress the posterior structures and aggravate a zygapophyseal extension dysfunction. Persistent or progressive pain in supine lying may indicate a neurogenic or space-occupying lesion, such as an infection, swelling, or tumor. It may also indicate a zygapophyseal extension dysfunction, especially if the patient has marked adaptive shortening of the hip flexors and rectus femoris. For women, back pain may show a monthly periodicity related to the menstrual cycle.

In addition to this list of basic questions, the clinician should also address the following areas:

- Patient's general health and past medical history. This component includes checking for a family history of rheumatoid arthritis, IVD lesions,[294] diabetes, osteoporosis, and vascular disease. When collecting information about the patient's health history, a useful acronym is "FAOMASHL": family health history, accidents, other associated/unassociated complaints, medications, allergies, surgeries, hospitalizations, and lifestyle factors.[271] The clinician should solicit information from the patient regarding the presence or past existence of any major illnesses, including, but not limited to, diabetes, heart disease, cancer, and hypertension. Any allergies should be documented. The dates, provider contact information, and outcomes of hospitalizations and surgical procedures should be noted.[271] It is also vital, from a diagnostic as well as treatment viewpoint, to determine the patient's level of conditioning.
- Patient age. Spondylolisthesis is more common among 10–20-year olds.[286,295] Cancer, compression fractures (see Chapter 5), spinal and lateral recess stenosis, and aortic aneurysms are more common among patients older than 65 years of age.[296,297] Inflammatory spondyloarthropathy, which can affect the spine, hips, knees, and feet, is most common in the 15–40-year-old age group,[224] and IVD lesions are more common in this group as well.[286] Osteoarthritis and spondylosis are more common in the 45 years and older age groups.[286] Effective medication can alter the disease course of spondyloarthropathies, making prompt diagnosis important. All patients under the age of 45 years with symptoms of more than 3 months should be asked four questions[298]:
  1. Does the morning back stiffness last over 30 minutes?
  2. Does the back pain awaken you during the second half of the night?
  3. Does the pain alternate from one buttock to the other?
  4. Does rest relieve the pain?

  If two out of the four questions are positive, there is a 70% sensitivity and 81% specificity for inflammatory back pain.[298] If three of four questions are positive, the sensitivity drops to 33%, but the specificity approaches 100%.[298]
- Occupation. Information regarding the patient's job description should include the estimated level of activity, from sedentary to strenuous.[271] Also, elements such as lifestyle factors, hobbies, and exercise routines can provide useful information. Flexion and rotation of the trunk, lifting, axial loading, sustained flexed postures, vibration, and low job satisfaction are all considered as risk factors for back pain.[299–301] The level of impairment or disability that a lesion produces is related to the type of work performed. For example, diskodural back pain produces more disability in a truck driver who has to sit the whole day than in a patient who has light and varying work. For some patients, normal activities are unrestricted but their favorite sport is impossible.[286] The clinician should determine if there are any work stressors that may either physically or emotionally delay recovery or increase the likelihood of chronicity.[271] This is necessitates a full understanding of the patient's job description and workplace environment. Depending on the circumstances, lifestyle factors may be a source of either physical or psychosocial irritation for the patient or can be used as a motivational force during treatment.[271] In addition, the patient's participation in hobbies may be negatively impacted by back pain. Recovery and return to these activities can also be used as a motivational device.[271]
- The impact of symptoms. The effect the symptoms have on the patient's work, daily activities, and recreational pursuits can be assessed using the functional assessment tests outlined later. With this information, the clinician can set a baseline with which to measure progress that is meaningful to the patient. In addition, the clinician can determine whether the need for assistive devices is warranted.

- Medication use. Pain medications can mask symptoms. If the patient reports taking pain medication prior to the examination, the clinician may not obtain a true response to pain from the patient. It is important to ask the patient about dosage and frequency of the over-the-counter preparations, prescription medications, particularly corticosteroids and anticoagulants, vitamins, and herbal supplements.

CLINICAL PEARL

In general, pain that is worse in the lower extremity than in the low back indicates a nerve root irritation, whereas pain that is worse in the low back than in the lower extremity is probably referred from a spinal structure.[276]

- Psychosocial factors and nonorganic signs. During the initial history, it is important to document any psychosocial factors or nonorganic signs and symptoms, as these may directly affect the clinician's ability to accurately and completely diagnose the patient (see "Examination Conclusions" section). The patient's response to treatment and prognosis will be impacted as well.

Systems Review

It must always be kept in mind that pain can be referred to the lumbar spine area from pathologic conditions in other regions. For example, reports of pain in the upper lumbar region could suggest the possibility of aortic thrombosis, neoplasm, chronic appendicitis,[302] ankylosing spondylitis, or visceral disease (see Chapter 5) (Table 28-8).

The clinician should determine whether there has been any recent and unexplained weight loss, night pain that is unrelated to movement, or changes in bowel and bladder function.

Any one of these findings may indicate the presence of a serious pathology:

- Unexplained weight loss or night pain not associated with movement may indicate a malignancy. In many patients whose LBP is caused by infection or cancer, the pain is not relieved when the patient lies down.[303] However, this finding is not specific for the presence of these conditions.[224]
- Bowel or bladder dysfunction may be a symptom of severe compression of the cauda equina (cauda equina syndrome). This is rare condition usually is caused by a tumor or a massive midline IVD herniation. Urinary retention with overflow incontinence is usually present, often in association with sensory loss in a saddle distribution, bilateral sciatica, and leg weakness.[224] This is condition constitutes a medical emergency.
- Unexplained abdominal pain and backache. Fielding et al.[304] in a review of 528 cases with abdominal aortic aneurysms reported that 91% had symptoms at their first presentation, with abdominal pain and backache being most common symptoms. In the same study, it was found that the diagnosis can be made by careful routine palpation deep and left to the midline keeping the hands steady in one position until the aortic pulse is felt, and then carefully evaluating the lateral extent of the pulse with the pads of the fingers.[305]

CLINICAL PEARL

An intriguing study by Roach et al.[306] that examined the sensitivity and specificity of historical questions to identify patients with serious pathology in the lumbar spine found the following questions to have the best positive likelihood ratios:

- Inability to urinate or to hold urine
- Sleep disturbances
- Current smoking history

It is important to note that although these questions were found to have very high specificity, they also had a very low true positive rate indicating that many of the patients with serious pathology did not answer "yes" to the historical questions. To improve sensitivity, while attempting to maintain moderate specificity in this study, a number of symptoms were considered in parallel. The highest combination of sensitivity (0.87) and specificity (0.50) was obtained by combining in parallel the symptoms of unable to sleep, awakened and unable to fall back to sleep, medication required to sleep, and pain worsened by walking.

Tests and Measures

Observation

Observation involves an analysis of the entire patient in terms of how he or she moves and responds, in addition to the positions the patient adopts. Whether the clinician chooses to greet patients personally in the waiting room or in the examination room, the examination should begin with the initial contact.[271] The patient's gait pattern and any antalgia can provide some important clues. Upper lumbar or thoracolumbar instability or hypermobility often can lead to facilitation of the upper lumbar segments, with resulting psoas hypertonicity.[283,307] This is may lead to reduced hip extension during gait, resulting in a shortened stride length on the involved side.[93] Body weight and ground reaction forces, generated by rapid walking, can equalize the stride length by hypermobilizing or destabilizing the lumbosacral junction or the ipsilateral sacroiliac joint.[93] The process is reinforced by the mechanical pull of the shortened iliopsoas, and this increases the stress on the upper lumbar spine, increasing the facilitation.

CLINICAL PEARL

Muscle weakness and reduced walking capacity are among several functional deficits associated with a lumbar herniated NP.[308,309] Weakness of the gastrocnemius is a clinical sign associated with involvement of the L5–S1 disk (neurologic level S1), whereas weakness of the extensor hallucis longus is a positive sign for involvement of the L4–5 disk (neurologic L5).

Once in the examination room, the patient should be gowned appropriately to allow complete inspection of the lumbar spine and lower extremities. Although spinal alignment provides some valuable information, a positive correlation has not been made between abnormal alignment and pain.[251,310] "Good posture" is a subjective term based on what the clinician believes to be correct, and it is highly variable (see Chapter 6).

Posterior Aspect. The shoulders and pelvis should appear fairly level, and the bony and soft-tissue contours should appear symmetric. A horizontal line through the highest points of the iliac crests also passes through the spinous process of the fourth lumbar vertebra. The transtubercular plane to the tubercles on the iliac crest cuts the body of the fifth lumbar vertebra, and the upper margin of the greater sciatic notch is the opposite spinous process of the first sacral vertebra. There should be no differences in the muscle bulk between both sides and regions of the erector spinae. Atrophy of the paraspinals is rare but may indicate a chronic inflammatory disease, such as ankylosing spondylitis or tuberculosis, or point to poliomyelitis or a myopathy.[273] If atrophy of the paravertebral or extremity muscles is present, the clinician must determine whether it follows a segmental or nonsegmental pattern. A predominance of the thoracolumbar portion of the erector spinae may indicate poor stabilization of this area,[137] or a rotational asymmetry.[311] Asymmetric spasm of the paraspinals or gluteal muscles can make them appear more prominent compared with the normal side. The presence of spasm should alert the clinician to the presence of sciatica or a serious disease.[273]

The inferior angles of the scapulae should be level with the seventh thoracic spinous process; the iliac crests should be level.[312] The PSISs, medial malleoli, and lateral malleoli should all be level with their counterparts on the opposite side. Differences between the two sides may indicate a functional limb-length discrepancy (see Chapter 29). This discrepancy can be caused by altered bone length, altered mechanics, or joint dysfunction[313] (Table 28-9).

The thoracic and lumbar vertebrae should be vertically aligned. The curvature of the spine is referred to as scoliosis (see Chapter 6).

Deformity, birthmarks, and hairy patches are all evidence of congenital deficits of the integumentary system and can indicate underlying anomalies in the systems derived from the same embryologic segments.[314] A hairy patch or tuft that is located at the base of the lumbar spine may indicate spina bifida occulta or diastematomyelia.[315]

Lateral Pelvic Shift. Structural asymmetry in the lumbar region often is associated with pain. For example, patients with disk-related LBP commonly present with a pelvic shift or list when acute sciatica is present. In these cases, the patient may list away from the side of the sciatica, producing a so-called sciatic scoliosis.[316] The lateral pelvic shift is perhaps the most commonly encountered. Under the McKenzie classification system (see Chapter 22), a derangement requires the presence of a relevant lateral shift deformity.[282] Determining the presence of a lateral shift deformity may help speed up the recovery from a derangement by first correcting the lateral shift deformity.[282] The direction of the list, although still controversial, is believed to result from the relative position of the disk herniation to the spinal nerve (Fig. 28-7). Theoretically, when the disk herniation is lateral to the nerve root, the patient may deviate the back away from the side of the irritated nerve, which has the effect of drawing the nerve root away from the disk fragment (Fig. 28-7). This movement is demonstrated dramatically in patients with extreme lateral disk herniations, whose efforts at side bending to the side of the herniation markedly exaggerate the pain and paresthesia.[317] When the herniation is medial to the nerve root, the patient may list toward the side of the lesion, in an effort to decompress the nerve root[318] (Fig. 28-7). It is also theorized that this is a protective position resulting from

- irritation of a zygapophyseal joint;
- irritation of a spinal nerve or its dural sleeve, caused by disk herniation[258] and the resulting muscle spasm[319];
- spasm of the quadratus lumborum muscle and, occasionally, the iliacus muscle; and
- the size of the disk protrusion. In a prospective study of 45 patients with a sciatic scoliotic list (Cobb's angle >4 degrees), Suk et al.[317] found that the direction of sciatic scoliosis was not observed during surgery to be associated with the location of nerve root compression, but rather it was related to the side of disk herniation. Porter and Miller[320] analyzed the mechanism of sciatic scoliosis and concluded that the herniated disk was thought to be reduced in size by stretching or inward bulging at the convex side of the scoliosis, and called this phenomenon autonomic decompression.[320]

The clinician must first determine the presence of the shift and then determine its relevance to the presenting symptoms. To determine its relevance, a side-glide test sequence can be used. The side-glide test sequence is performed by manually correcting the shift by pushing the pelvis into its correct position[282] (Fig. 28-8). VIDEO If the side-glide produces either a centralization or peripheralization of the patient's symptoms, the test is considered positive for a relevant lateral shift.[321] In addition, for a lateral shift to be significant, the patient must exhibit an inability to self-correct past midline when asked to shift in the direction opposite the shift.[322] The relevant lateral shift must be corrected, using side-glides, before the patient attempts the McKenzie extension exercises.[323] A lateral shift

that is not deemed to be relevant or to be a deformity, per McKenzie criteria, may be treated with only sagittal plane movements (e.g., extension principles).[282]

CLINICAL PEARL

Riddle and Rothstein found that therapists agreed 60% of the time on the presence and direction of the lateral shift. A κ value of 0.26 was determined, indicating poor reliability.[324] A similar study by Donahue et al. of 49 patients with LBP examined the amount of intertester agreement when assessing only the lateral shift. The amount of agreement was found to be 47%, statistically similar to that obtained by pure chance.[322]

FIGURE 28-8 Side-glide test.

Lateral Aspect

From the side, the clinician should observe that the ear lobe should be in line with the tip of the shoulder, and the peak of the iliac crest. T e amount of lumbar lordosis is noted as to whether it is excessive or reduced. T e lumbar lordosis should appear as a smooth and gentle curve, and there should be a gradual transition at the thoracolumbar junction.

- An excessive lordosis may result in the pelvic crossed syndrome.[137] In this syndrome, the erector spinae and the iliopsoas are found to be adaptively shortened, and the abdominal and gluteus maximus muscles are found to be weak. As a result, this syndrome can produce adaptive shortening of the PLL, lower-back extensors, and hip flexor muscles and lengthening of the ALL and lower abdominals. An excessive lordosis may also indicate that the patient has a spondylolisthesis. With this condition, the whole spine often lies in a plane anterior to the sacrum. T ere may also be an associated mid or low lumbar shelf at the spinous processes, which, if not visible, can be palpated. An anterior pelvic tilt posture may also be caused by weakness of the abdominal muscles or an adaptively shortened iliopsoas or TLF, with subsequent lengthening of the hamstring and gluteal muscles.[137]
- A flattened back may indicate that the patient has either a lumbar spinal stenosis, a lateral recess stenosis, or some lateral shifting of the spinal column. A flattened lordosis may be caused by a posterior pelvic tilt, adaptive shortening of the hamstrings, disk protrusion, and weakness of the hip flexor muscles.[137]
- A reversed lordosis, often referred to as a sway back, is caused by a thoracic kyphosis and a posterior pelvic tilt. T is posture results in a stretching of the anterior hip ligaments, back extensors, and hip flexors; hip hyperextension; and compression of the vertebrae posteriorly.[137] Kyphosis of the lumbar spine may also indicate damage to the SSL complex.

T e type of footwear that the patient habitually wears can be a factor. For example, high-heeled footwear has a tendency to modify the pelvic angle and increase the lordosis.[325]

Palpation

There is some disagreement as to when in the examination the palpation assessment should occur, with some authors preferring to perform this portion at the end.[326] The order of examination procedures should reflect an awareness of the patient's potential discomfort and proceed from least to most invasive.[271] For instance, a patient who reports difficulty when lying on his or her stomach should be examined in the prone position only if necessary, saving this position for the end of the examination. For patients who are able to attain all positions without significant distress, it is most convenient for the clinician to perform procedures as gravity suggests, moving from the standing position to seated, supine, side lying, and then prone.[271]

Whenever it is performed, palpation of the lumbar spine area should be performed in a systematic manner, and in conjunction with palpation of the pelvic area, which is described in Chapter 29, and the hip area, which is described in Chapter 19. Palpation of the lumbar region is best performed with the patient in a prone position but may also be performed on a seated or standing patient. The examiner should begin by assessing the soft tissues for an increase in focal temperature.[271]

CLINICAL PEARL

A study by Deyo et al.[224] found that palpation of soft tissue and bony tenderness had both pool reproducibility and specificity.

As previously mentioned, in most individuals, the midpoint of an imaginary line drawn between the iliac crests represents the L4–5 interspace and the level of the L4 transverse process. The transverse processes of L3, L2, and L1 each lie two fingerbreadths superior to the vertebra, respectively.[327] Alternatively, they can be found at the level of the lower pole of the spinous process of the vertebra immediately above or below. The lumbar zygapophyseal joints of each motion segment are located approximately 2–3 cm (0.8–1.2 in) lateral from the spinous processes. The reference point indicating the position of L4 is marked on the patient. The spinous process of L5 is just inferior to this point. The L5 spinous process is short, sharp, and thick compared with those of L4 and L3. The clinician should move superiorly from the L5 spinous process, carefully palpating each segmental level. Evidence of tenderness, altered temperature, muscle spasm, or abnormal alignment during palpation can highlight an underlying impairment.

Posterior Aspect

Palpation of the posterior aspect of the lumbar spine is best achieved by placing the patient in a relaxed prone position, or bent over the treatment table.

- The clinician moves the index and middle fingers quickly down the spine, feeling for any abnormal projections or asymmetries of the spinous processes. Any alterations in the alignment of the spinous processes in a posteroanterior (P-A) direction, particularly at the L4–5 or L5–S1 segmental level may indicate the presence of a spondylolisthesis.[328] Specific pain elicited with P-A pressure over the segment serves as further confirmation. Asymmetry of the spinous processes in a P-A direction may also indicate wedging of a vertebral body or a complete loss of two adjacent IVD spaces.[273] Absence of a spinous process may be associated with spina bifida. Side-to-side alterations in the spinous process may indicate the presence of a rotational asymmetry of the vertebra.[311]
- The SSLs should be palpated. The ligament is usually supple, springy, and nontender. Because this ligament is the most superficial of the spinal ligaments and the farthest from the axis of flexion, it has a greater potential for sprains.[70]
- Palpation of the transverse processes of T12 and L5 presents difficulties. That of L3 is easy to feel, being usually the longest of all transverse processes; it is usually possible to feel those of L1, L2, and L4. That of L5 is covered by the posterior ilium.[329]
- Patients with localized tenderness over the zygapophyseal joints without other root tension signs or neurologic signs may have zygapophyseal joint pain.[330] This source can be confirmed if the patient responds well to intraarticular joint injections or to blocks of the medial branches of the posterior (dorsal) rami[330,331]
- A well-localized and tender point at the gluteal level of the iliac crest, 8–10 cm from the midline, may indicate the presence of Maigne's syndrome.[319] Maigne's syndrome is characterized by sacroiliac joint, low lumbar, and gluteal pain, with an occasional referral to the thigh, laterally or posteriorly.
- Normally, the skin can be rolled over the spine and gluteal region with ease. Tightness or pain produced by skin rolling may indicate some underlying pathology.[332] The source of the signs and symptoms is an irritation of the medial cutaneous branch of posterior (dorsal) rami of the T12 or L1 spinal nerves, as it passes through a fibro-osseous tunnel at the iliac crest.[319]

Anterior Aspect

- The inguinal area, located between the ASIS and the symphysis pubis, should be palpated carefully for evidence of tenderness, which may be indicative of a hernia, an abscess, sprain of the ligament, or an infection, if the lymph nodes are swollen and tender.
- In some patients, the anterior aspect of the vertebral bodies may be palpable when the patient is positioned supine with the hips flexed and feet flat on the bed. Tenderness of the anterior aspect of the vertebral bodies may indicate an irritation of the ALL, which may indicate the presence of an anterior instability.[333]

CLINICAL PEARL

Evaluation of the abdominal, inguinal, popliteal arteries, and distal pedal pulses is dependent on the patient's profile and presentation.[271] As a general rule, the abdominal aorta should be assessed for possible enlargement via auscultation and palpation in any patient over the age of 50 with acute onset of LBP.[271]

TABLE 28-10 Normal Active ROM of the Lumbar Spine	
Movement	**Range (Degrees)**
Flexion	50–70
Extension	10–30
Side bending	25–35
Axial rotation	20–40

Data from Ng JK, Kippers V, Richardson CA, et al. Range of motion and lordosis of the lumbar spine: Reliability of measurement and normative values. Spine. 2001;26:53–60.

Active Range of Motion

Normal active motion, which demonstrates considerable variability (Table 28-10) between individuals, involves fully functional contractile and inert tissues and optimal neurologic function.[150,334–337] It is important to note that ROM may be affected by age and sex, whereas occupation and body mass index have little or no influence on the motion.[338] In addition it has also been determined that total sagittal ROM, flexion angle, and extension angle decline as age increases.[339] However, it is the quality of motion, and the symptoms provoked, rather than the quantity of motion, that are more important. The reproducibility (precision) of an individual's effort is one indicator of optimum effort. Measurements should not change significantly (< 5 degrees) with repeated efforts.[340] The capsular pattern for the lumbar spine is normal trunk flexion, a decrease in lumbar extension with rotation, and side bending equally limited bilaterally.[341]

A good view of the spine is essential during motion testing. External measurement of vertebral motion may not reflect the true intervertebral movement because of skin movement error,[342] but it is less invasive than a radiograph and more practical. Although limited spinal motion is not strongly associated with any specific diagnosis, this finding may help in the planning or monitoring of the physical therapy intervention.[224]

CLINICAL PEARL

Among the spinal motion tests, rotation, side bending, and fingertip-to-floor distance show the strongest associations with the severity of back pain.[342]

While standing, the patient performs flexion, extension, and side bending to both sides (Fig. 28-9A–D). Pain induced by active ROM may implicate a number of tissues including muscle and tendon, ligament and capsule, and bone and nerve.

The active ROM tests should be observed in front of and behind the patient. At the end of each of the active motions, passive overpressure is applied to assess the end-feel, and then resistance tests are performed with the muscles in the lengthened positions. The key to deciphering which offending structure is involved lies in determining the type of pain produced and whether active, passive, and/or resisted motions are provoking. Injuries involving noncontractile tissues such as ligaments, facet capsules, and IVDs are provoked by loading the structure actively or passively, whereas resisted isometric muscle contraction is typically unprovoking, unless, in the case of disk herniation, "abdominal canister" (i.e., transversus, obliques, rectus, multifidi, pelvic floor, and diaphragm) contraction increases intrathecal pressure.[271]

During the active motions, the clinician notes the following:

- **The curve of the spine.** The curve of the spine in flexion, extension, and side bending should be smooth. An angulation occurring during flexion or extension could indicate an area of instability or hypomobility. In side bending, an angulation indicates hypomobility below the level or hypermobility above the level in the lumbar spine.[332]
- **Provocation of symptoms.** The clinician should determine whether the symptoms are neurologic or nonneurologic, and how far the distribution of pain extends. Leg pain provoked by any motion other than flexion is not a good prognostic sign[341]; neither is posterior leg pain, reproduced with extension, rotation, or side bending, as this usually indicates a significant disk prolapse or extrusion.
- **Any gross limitations of motion.** Gross limitation of both side bends may indicate ankylosing spondylitis or significant osteoarthritis.
- **The presence of any deviations during or at the end of the range.** Deviations of, or aberrant, movement include the presence of any of the following: painful arc with flexion or return from flexion, instability catch, Gower sign, and reversal of lumbopelvic rhythm.[11] Failure to recover from flexion smoothly may indicate instability.[343,344] This is typically occurs at the endpoint of flexion, as the patient begins to return to the erect stance and has to extend the lumbar spine by walking the hands up the thighs (Gower's sign). A sudden acceleration, stop, deceleration, a momentary quiver, vibration, or shake may indicate instability. Trunk deviation from the sagittal plane during flexion is believed to be associated with a disk herniation, with the direction of the deviation being determined by the relative position of the compression on the nerve. How the disk responds to movements depends on the activity. For example, walking appears to move the NP into a more central location, whereas prolonged sitting appears to displace the disk into a less advantageous position.[345] An altered lumbopelvic rhythm is defined as hip motion greater than lumbar spine motion during the first third of the flexion movement, and/or lumbar spine motion greater than hip motion during the last third of the flexion movement. During the return to the upright position, lumbar spine motion greater than hip motion during the first third of the movement and/or hip motion greater than lumbar spine motion during the last third of the movement also indicates altered lumbopelvic rhythm.

Both O'Sullivan[333] and Sahrmann[346] have devised classification schemes to categorize dysfunctional movement patterns:

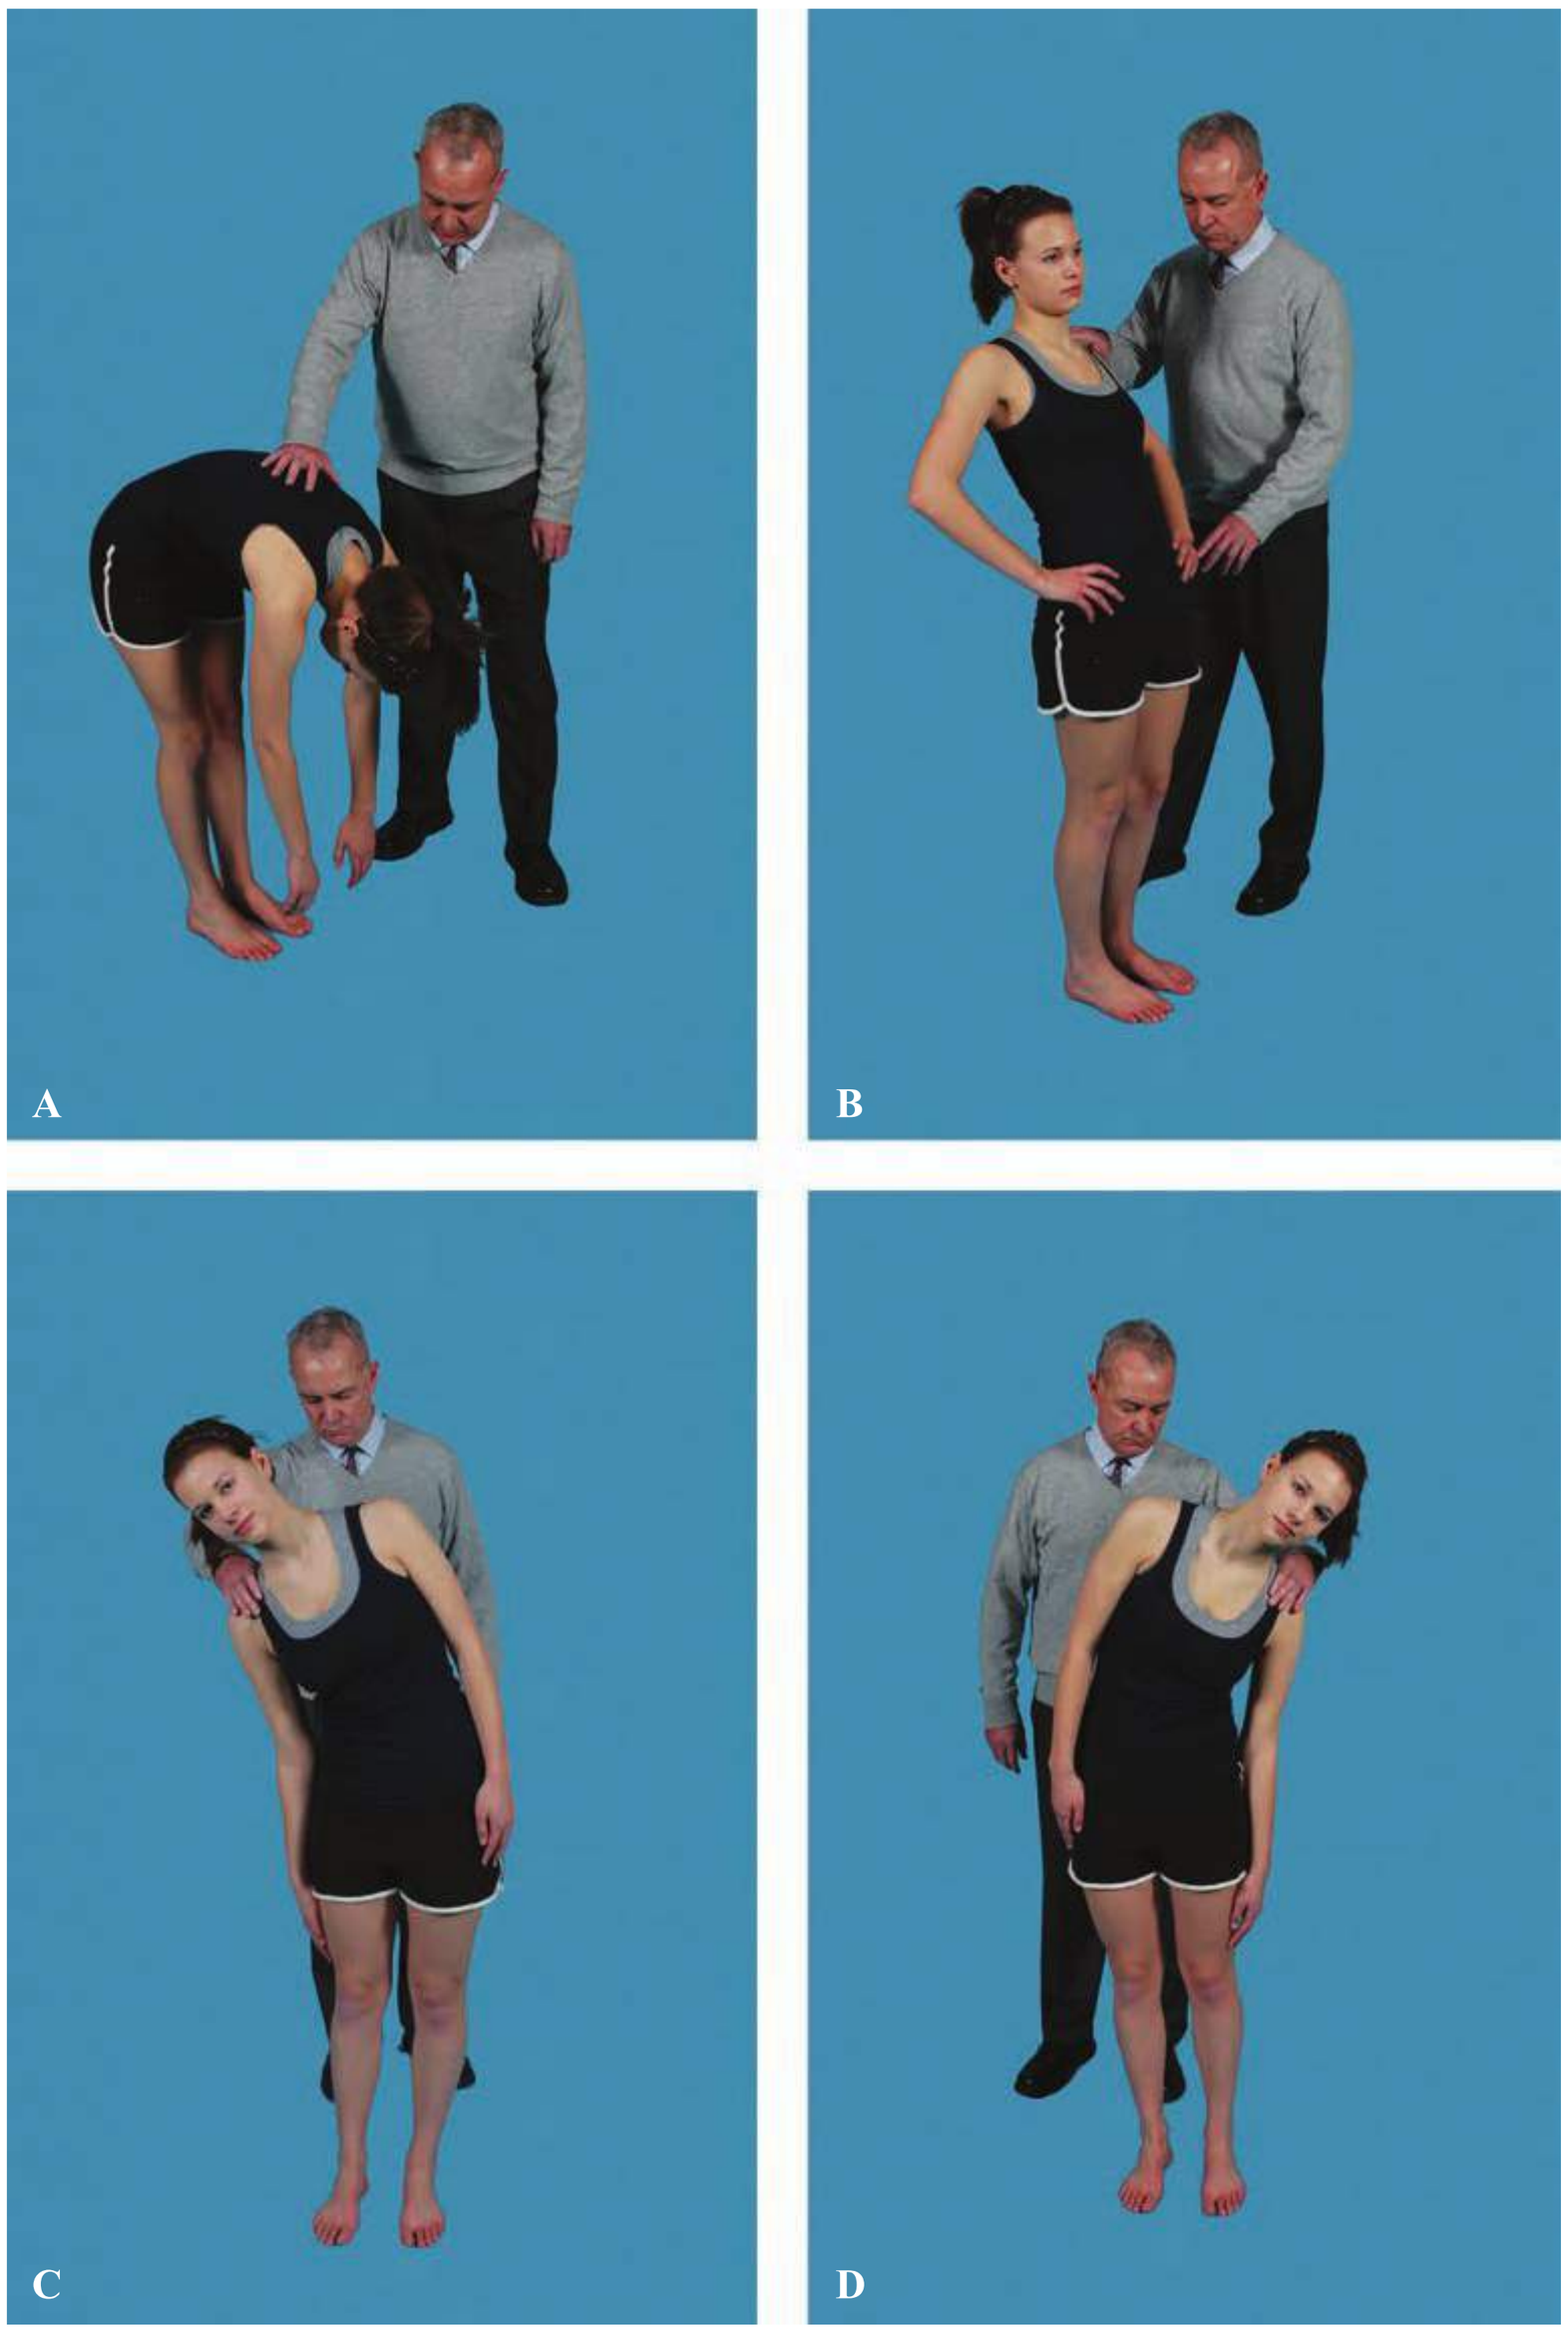

FIGURE 28-9 Active ROM of the lumbar spine with overpressure. A: Flexion. B: Extension. C: Side bending right. D: Side bending left.

O'Sullivan classifies instabilities according to directional patterns of clinical instability, although he admits that these classifications have not been scientifically validated.[333]

- Flexion pattern. The flexion pattern is the most common. It is characterized by complaints of central back pain that is aggravated by flexion–rotational movements, and an inability to sustain semiflexed positions. On observation, there is often a loss of segmental lordosis at the level of the "unstable" motion segment, which is more noticeable in standing. This loss of lordosis is increased in flexed positions. Movements of forward flexion are associated with a tendency to flex more at the symptomatic level than at adjacent levels and, usually, are associated with an arc of pain into flexion and an inability to return from flexion to neutral without use of the hands to assist in the movement. During backward bending, extension above the symptomatic segment, with an associated loss of extension at the involved segment, often is observed. Functional activities, such as squatting, sitting with knee extension or hip flexion, and sit to stand, reveal an

inability to control a neutral lordosis and a preponderance to segmentally flex at the unstable motion segment. Specific muscle tests reveal an inability to perform the abdominal hollowing maneuver (see "Clinical Instability of the Lumbar Spine" section) at the unstable motion segment. The patient may also be unable to actively produce a neutral lordotic lumbar spine posture.

- Extension pattern. The extension pattern is characterized by complaints of central back pain that is aggravated during extension–rotational movements, and an inability to sustain positions such as standing, overhead activities, fast walking, running, and swimming. On observation, there is often an increase in segmental lordosis at the level of the "unstable" motion segment in standing, which is often associated with an increase in segmental muscle activity at this level. Extension activities reveal segmental hinging at the involved segment, with a loss of segmental lordosis above this level and an associated postural sway. Forward bending movements often reveal a tendency to hold the lumbar spine in lordosis, with a sudden loss of the lordosis midway through the flexion range and an arc of pain. On returning from the flexed position, there is often a tendency to hyperextend the lumbar spine segmentally before the upright posture is achieved, with pain on returning to the upright position. Specific muscle testing reveals an inability to perform the abdominal hollowing maneuver. The patient also is often unable to initiate a posterior pelvic tilt independent of hip flexion and activation of the gluteal muscles, rectus abdominis, and external obliques.
- Recurrent lateral shift pattern. The lateral shift is usually unidirectional, occurs recurrently, and is associated with unilateral LBP. The patient typically stands with a loss of lumbar segmental lordosis at the involved level and an associated lateral shift at the same level. The lateral shift is accentuated when standing on the foot ipsilateral to the shift and is observed during gait as a tendency to transfer weight through the trunk and upper body rather than through the pelvis. Sagittal spinal movements reveal a shift further laterally at midrange flexion, which is commonly associated with an arc of pain. Sit to stand and squatting are associated with a tendency toward lateral trunk shift during the movement, with increased weight bearing on the lower limb ipsilateral to the shift. Specific muscle testing reveals an inability to perform the trunk raise, with dominance of activation of the quadratus lumborum, lumbar erector spinae, and superficial multifidus on the side ipsilateral to the shift and an inability to activate the segmental multifidus on the contralateral side to the lateral shift.
- Multidirectional pattern. This pattern is the most serious and debilitating of the patterns and is frequently characterized by high levels of pain and functional disability. All weight-bearing positions are normally painful, and locking of the spine frequently occurs with positions of sustained flexion, rotation, and extension. These patients exhibit great difficulty in assuming neutral lordotic spinal positions, and an inability to perform the abdominal hollowing maneuver.

Sahrmann categorizes a number of movement impairment syndromes that can present in the lumbar spine as a result of an imbalance of flexibility and strength. The intervention for each of the syndromes involves a correction of these imbalances.

- Flexion syndrome. This syndrome is characterized by lumbar flexion motions that are more flexible than hip flexion motions. The syndrome is typically found in the 8–45-year-old age range and results in pain with positions or motions associated with lumbar flexion, because of adaptive shortening of the gluteus maximus, hamstrings, or rectus abdominis.
- Extension syndrome. This syndrome is characterized by lumbar extension motions that are more flexible than hip extension motions. Patients with this syndrome are usually older than 55 years of age, and the symptoms are increased with positions or motions associated with an increase in lumbar lordosis, because of adaptive shortening of the hip flexors and lumbar paraspinals and weakness of the external oblique muscles.
- Lumbar rotation. This syndrome is characterized by pain that is unilateral or greater on one side and is increased with rotation to one side. No attempt is made to equate the side of rotation with the side of the symptoms. It is theorized that this syndrome is produced when one segment of the lumbar spine rotates, side bends, glides, or translates more easily than the segment above or below it. This syndrome is associated with spinal instability and can result from habitual motions or positions that involve rotation to one side, a leg-length discrepancy (see Chapter 29), or a muscle imbalance between the oblique abdominal muscles.
- Lumbar flexion with rotation. This syndrome is characterized by pain that is unilateral or greater on one side and is increased with the combined motion of lumbar flexion and rotation. Many of the characteristics of the lumbar flexion and lumbar rotation syndromes can be applied to this syndrome.
- Lumbar extension with rotation. This syndrome is characterized by pain that is unilateral or greater on one side and is increased with the combined motion of lumbar extension and rotation. Many of the characteristics of the lumbar extension and lumbar rotation syndromes can be applied to this syndrome.

The clinician should also consider having the patient remain at the end range of each of the motion tests for 10–20 seconds if sustained positions were reported to increase the symptoms. If repetitive or combined motions were reported in the history to increase the symptoms, the patient is asked to perform repeated motions. McKenzie[282] advocates the use of sustained or repeated movements of the spine in an attempt to affect the nuclear position. These movements are performed either to peripheralize the symptoms lateral from the midline or distally down the extremity or ideally to centralize the symptoms to a point more central or near the midline. One study of 87 patients with leg and LBP[291] found that those patients who demonstrated excellent outcomes with the McKenzie-based interventions had reported centralization during the initial examination. Another study[292] found

a significant correlation between positive diskograms and peripheralization and centralization, with the incidence of an adequate annulus being significantly greater in the centralizing patients with positive diskograms than in their peripheralizing counterparts.

There is no gold standard to measure ROM of the lumbar spine. The majority of published data concerning normal ranges of motion exists without concomitant data on the subjects' demographic background, specifically with respect to age, gender, and occupation. Methods to objectively measure lumbar motion have included[335]:

- Measuring the ROM visually (eyeballing). This method is endorsed by the American Academy of Orthopaedic Surgeons.[347] Although this seems to be the fastest and easiest method, its validity is questionable.[348]
- Using a tape measure, measuring the distance from a bony landmark to the floor at the end of the available motion. This test provides only a gross measurement of the lumbar motion.[349]
- Goniometric measurement. The goniometer, also known as the universal goniometer, is the most accessible and least costly device. It should be noted that goniometric measurement of the lumbar spine often incorporates some thoracolumbar motion. It should also be noted that researchers have found poor intra- and interrater reliability for all goniometric measurements of the thoracolumbar spine.[350–352] Table 28-11 lists the suggested landmarks used when assessing lumbar ranges of motion with a goniometer.
- Schöber technique. This technique is used only to measure flexion. The first sacral spinous process is marked, and a mark is made about 10 cm above this mark. The patient then flexes forward, and the increased distance is measured. If there is a normal motion of the lumbar spine with an absence of disease, there should be an increase of 4–5 cm. The obvious limitation of this technique is that it only measures flexion.
- The modified Schöber technique,[353] which measures the change in distance between two skin markings over the lumbar spine during flexion or extension. A point is marked midway between the two PSISs, which is the level of S2. Points at 5 and 10 cm above that level are marked, and the distance between the three points is measured. The patient is asked to bend forward or backward, and the distance is remeasured. The distance between the two measurements is an indication of the amount of motion occurring in the lumbar spine. This method also is prone to error, because it can measure lower lumbar levels only and may not reflect the amount of motion available in the whole lumbar spine.[354] Various studies have shown this technique to have overall good interrater reliability.[354,355]
- The fluid (bubble) goniometer. This device consists of a fluid-filled circular tube attached to or embedded in a flat platform with a 360-degree scale. With the joint in a neutral position, the device is either strapped to the distal aspect of an extremity or manually held in place on the patient, as can be the case when measuring trunk movement. Although many clinicians appreciate the ease of use and elimination of landmark estimation required by the universal goniometer, this device still exhibits problems with reliable positioning, particularly if attached with a strap or when used on obese patients.[271] Landmarks used are similar to those of the goniometer's active arm.
- The inclinometer technique recommended by the American Medical Association.[340] Inclinometers are small angle measuring devices that work like a plumb line, operating on the principle of gravity. An appropriate inclinometer should include a large enough dial to allow easy reading of 2-degree increments. For example, to measure lumbar flexion, two inclinometers are used, aligned in the sagittal plane. The center of the first inclinometer is placed over the T12 spinous process at the thoracolumbar junction to assess the total flexion measure. The center of the second one is placed over the sacrum, midway between the PSISs to assess motion at the sacroiliac joints and hip joints. The patient is asked to flex the trunk as far as possible, and both inclinometer angles are recorded. The lumbar flexion angle is calculated by subtracting the sacral (hip) from the T12 inclinometer angle. The difference in motion represents the lumbar flexion measure.[11] The patient is then asked to bend backward, and the difference in motion is the lumbar extension measure. A similar process is used for side bending with the inclinometer aligned in the frontal plane, and the patient is asked to bend to each side.[11] In a

TABLE 28-11 Goniometric Landmarks, Normal Motion Values, and End-Feel Descriptors for the Lumbar Spine

Motion	Axis of Rotation	Arm Landmarks	Normal Values (Degrees)	Normal End-Feel
Flexion	Coronal/axillary line at L5 level	Stationary arm: along thigh Active arm: axial line to L1 spinous process	70–90	Tissue stretch (firm elastic resistance)
Extension	Coronal/axillary line at L5 level	Stationary arm: along thigh Active arm: axial line to L1 spinous process	30–50	Bone to bone (hard, painless) or tissue stretch
Side bending	Midline at S1 spinous process	Stationary arm: midline inferiorly Active arm: L1 spinous process	30	Tissue stretch
Rotation	Visual estimation only		35	Tissue stretch

study by Saur et al.,[356] this method approximated lumbar motion obtained with the radiographic measures (r = 0.93 overall; r = 0.95 with flexion and r = 0.85 with extension). Interrater (physician and physiotherapist) reliability was r = 0.884 with flexion (standard error of measurement, 4.6 degrees) and r = 0.42 with extension (standard error of measurement, 2.3 degrees). Another similar technique has been described in which total flexion and extension are recorded. T e inclinometer is placed and zeroed at the thoracic or lumbar junction, and then the subject bends forward. T e total flexion is recorded. T e subject bends backward, and the total extension is recorded.

Whatever technique is chosen, the same technique must subsequently be used when reassessing ROM.

Flexion. T e first 60 degrees of forward bending typically result from flexion of the lumbar motion segments, which is followed by an additional movement at the hip joints of approximately 25 degrees.[60] T e patient is instructed to tuck the chin toward the chest and bend forward at the waist, keeping the knees extended, while attempting to touch the toes.[271] T e clinician should note any change in an existing scoliotic curve, deviation away from the midline which may suggest guarding due to disk pathology, patient apprehension or assistance (use of hands on knees), which may suggest instability, lack of motion between spinal segments, and whether the normal lordosis decreases as expected.

T e lumbar flexion movement can be repeated with the patient sitting, as this test can help screen for the presence of rotoscoliosis.[357]

McKenzie[282] advocates the testing of lumbar flexion motion in supine as well as in the standing position. In the standing position, flexion of the lumbar spine occurs from above downward, so pain at the end of the range is likely to indicate that L5–S1 is affected. Bringing the knees to the chest in the supine position (Fig. 28-10) produces a flexion of the lumbar spine from below upward, so that pain at the beginning of the movement may indicate that L5–S1 is affected.[282]

Trunk deviation during flexion is believed to be associated with an IVD herniation, with the direction of the deviation determined by the relative position of the compression on the nerve.[358] Deviations during flexion may also result from neuromeningeal adhesions, hypomobile segment(s) on the contralateral side, hypermobile segment(s) on the ipsilateral side, a structural scoliosis, and a shortened leg on the ipsilateral side.[358] Passive ROM is tested with the patient seated on the examination table. T e patient is instructed to keep the arms to the side, while the clinician grasps his or her shoulders and flexes the patient forward at the waist, keeping the pelvis firmly on the table. T e clinician should note the end-feel and any change in an existing scoliotic curve, lack of motion between spinal segments, and whether the normal lordosis decreases as expected.

FIGURE 28-10 Lumbar flexion from below.

Extension. T e patient is instructed to place his or her hands on the posterior iliac crests to provide support and then extend backward from the waist, keeping the knees extended and the gaze toward the ceiling (Fig. 28-9B). T e clinician notes if the arc of extension is even throughout the lumbar spine or more pronounced at a specific spinal segment.[271] Pure lumbar extension in standing involves the patient leaning back at the waist. Lumbar extension is often the stiffest and most uncomfortable movement for the patient. T us, patients with LBP tend to use the protective guarding mechanism against the compression and shearing forces, generated by simply hyperextending the hips. By applying a compressive force to the patient's shoulders during the backward bending, the clinician can induce a small increase in the lumbar lordosis. Passive ROM is tested with the patient seated on the examination table. T e patient is instructed to place his or her hands across the chest. T e clinician supports the upper back with one arm and the sacrum with the other hand and then extends the patient backward in an arching motion rather than a leaning motion. T e clinician notes the end-feel or any altered symptoms.

Side Bending. T e standing patient is instructed to lean to the side by sliding the palm of the hand down the outside of the thigh, without flexing forward or extending backward, and keeping the palm on the lateral thigh or hip. T e clinician notes if the arc of bending is even or more pronounced at a specific spinal segment as well as whether the patient unintentionally rotates the torso to accommodate the motion.[271] Side-bending ROM has been found to be a good indicator of the degree of LBP[230] and disability.[231] In acute spinal derangements, such as a unilateral posterolateral IVD protrusion or unilateral zygapophyseal joint derangement, lumbar side bending may be significantly reduced or absent on one side (usually toward the involved side). Arthritic conditions of the spine tend to demonstrate a symmetric loss of side bending to both sides.

T e common method of measuring the amount of side bending is to record the distance between the fingertip and the floor at the end of the side bend, but this is merely an estimation of the flexibility of the whole spine rather than the lumbar spine.[335] T us, it is recommended that lumbar spine movement in side bending be measured using the inclinometer technique.[340]

T e patient may be seen to lift one foot or bend the knees during the side-bending movements and should be reminded to maintain the feet on the floor during measurement. At the end of the side-bending motion, overpressure is applied on the shoulder (see Fig. 26-9C–D). Passive ROM is tested with the patient seated on the examination table. T e patient is instructed to cross the arms across the chest. T e clinician

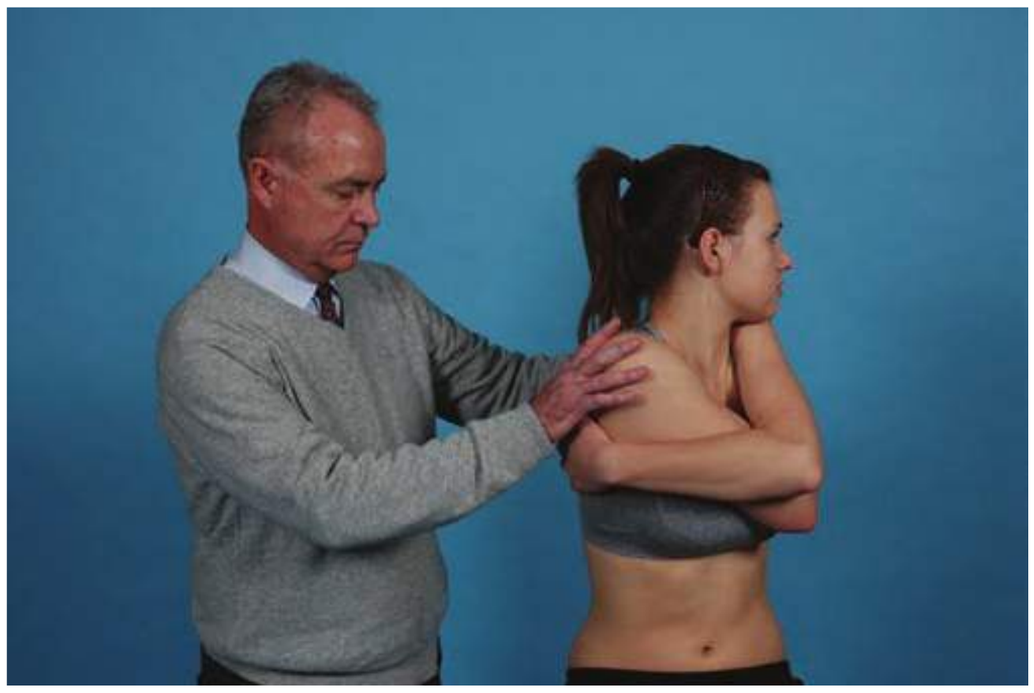

FIGURE 28-11 Lumbar rotation.

places one arm across the upper back and the other hand on the contralateral iliac crest. The clinician then bends the patient to each side, keeping the opposite crest from rising off the table. As with extension, an arching motion rather than a leaning motion is desired. The end-feel is noted or any altered symptoms.

Axial Rotation. Axial rotation of the spine usually is assessed in the sitting position to eliminate motion occurring from the hips. The patient, keeping the knees together, twists at the waist to each side. Patients frequently tend to side bend or extend the torso, so the clinician must take care in preventing such motion. Axial rotation of the trunk commonly includes movement of both thoracic and lumbar segments of the spine. Overpressure may be applied at the end of the range (Fig. 28-11). Normal range could indicate normalcy, hypermobility, or instability. The restricted range will be in either a capsular or a noncapsular pattern. Pain with this maneuver can implicate a nonorganic source, an annular tear, a ligament tear, or a zygapophyseal joint dysfunction.[358] Passive ROM is tested with the patient seated on the examination table. The patient is instructed to place his or her hands across the chest, and the clinician grasps the shoulders and rotates the patient's torso. Alternately, the clinician may use a shoulder–scapula contact. End-feel is noted or any altered symptoms.

Combined Motion Testing. The combined motion tests of the lumbar spine are used to detect biomechanical impairments. Although combined motion tests do not provide information as to which segment is at fault, they may provide information as to which motion or position reproduces the pain.[359]

Combined motion tests can reproduce the pain in a structure that is either being compressed or stretched[360]:

- A reproduction or increase in symptoms with flexion and side bending away from the side of the symptoms may implicate pain in a structure that is being stretched.
- A reproduction or increase in symptoms with extension and side bending toward the side of the symptoms may implicate pain in a structure that is being compressed.

Combined motions can be performed as repetitive motions or as sustained positioning. For example, the patient can be asked to perform the combined motion of flexion and right side bending repetitively to assess for what McKenzie describes as a derangement syndrome or the clinician can position the patient in flexion and right side bending (Fig. 28-12) to assess for what McKenzie describes as a dysfunction syndrome. Alternatively, the clinician can ask the patient to maintain the position of flexion and right side bending to assess for a postural dysfunction.[282]

FIGURE 28-12 Lumbar flexion and right side flexion.

Van Dillen et al.[361] recommend a clinical examination based on the movement system impairment (MSI) model, which includes tests of movements and positions in which judgments of lumbar movement and alignment are made, and symptoms are assessed. For movement or positions that reproduce LBP symptoms, the test is repeated with a standardized manual correction of lumbar movement or alignment (i.e., to limit that particular direction of lumbar motion observed with the test, or to position the patient in a neutral alignment) and symptom behavior is reassessed.[362] Based on the results obtained from the tests and the specific corrective measures applied, clinicians can classify patients with LBP into one of five subgroups, named for the directions of lumbar movement and alignment (flexion, extension, or rotation) that appear to contribute to the LBP.[362]

As the hip has long been identified as a potential source of, and contributor to, LBP and impairments in hip mobility have been found to be associated with the presence of LBP,[11,363–366] a thorough assessment of hip mobility should occur, especially if the results of the lumbar ROM are inconclusive.

Six-Position Test

The six-position test is a type of MSI screening tool that I have found to be particularly useful with the acute patient, in helping to determine the position of comfort for the patient and for focusing the examination and intervention. The reliability

FIGURE 28-13 Supine lying.

FIGURE 28-15 Double knees to chest.

or validity of these tests has yet to be established, but they are based on applied anatomy and biomechanics. T e patient is placed in the following positions:

1. Supine with the hips and knees extended (Fig. 28-13). In individuals with adaptive shortening of the rectus femoris and the iliopsoas (a common finding), this position is manifested by an inability of the posterior thighs to rest on the table. Pain in this position may indicate a lumbar extension or lumbar rotation syndrome (see "Intervention Strategies" section), especially if the next position relieves the symptoms.[346]
2. Supine in the hook-lying position, with the hips and knees flexed and the feet flat on the bed (Fig. 28-14). T is is typically the most comfortable position for the patient with acute LBP, except in cases of severe lateral recess stenosis or spondylolisthesis.
3. Supine with both knees held against the chest (Fig. 28-15). T is position rotates the pelvis posteriorly and widens the intervertebral foramina of the lumbar segments.[290] T is is normally a comfortable position for patients who have lateral recess stenosis, or a lumbar extension syndrome.
4. Supine with one hip and knee extended, the patient raises the other knee to the chest without using the arms (Fig. 28-16). Once the leg is elevated, the patient grasps it with both hands and pulls it toward the chest. Holding the left knee against the chest invokes a position of lumbar flexion and left side bending, which widens the intervertebral foramen on the right and narrows the intervertebral foramen on the left. Holding the right knee against the chest invokes a position of lumbar flexion and right side bending, which widens the intervertebral foramen on the left and narrows intervertebral foramen on the right.[290] Given the amount of rotation induced by this maneuver, this test is often positive even when the position of both knees to the chest does not provoke symptoms. Occasionally, though, one side may be pain free and can be used as an introductory exercise.
5. Prone lying with the legs straight (Fig. 28-17). T is is typically comfortable for patients with an IVD protrusion, but uncomfortable for patients with spinal lateral recess stenosis, spondylolisthesis, and an extension or a rotation syndrome[346] (see "Intervention Strategies" section).

FIGURE 28-14 Hook lying.

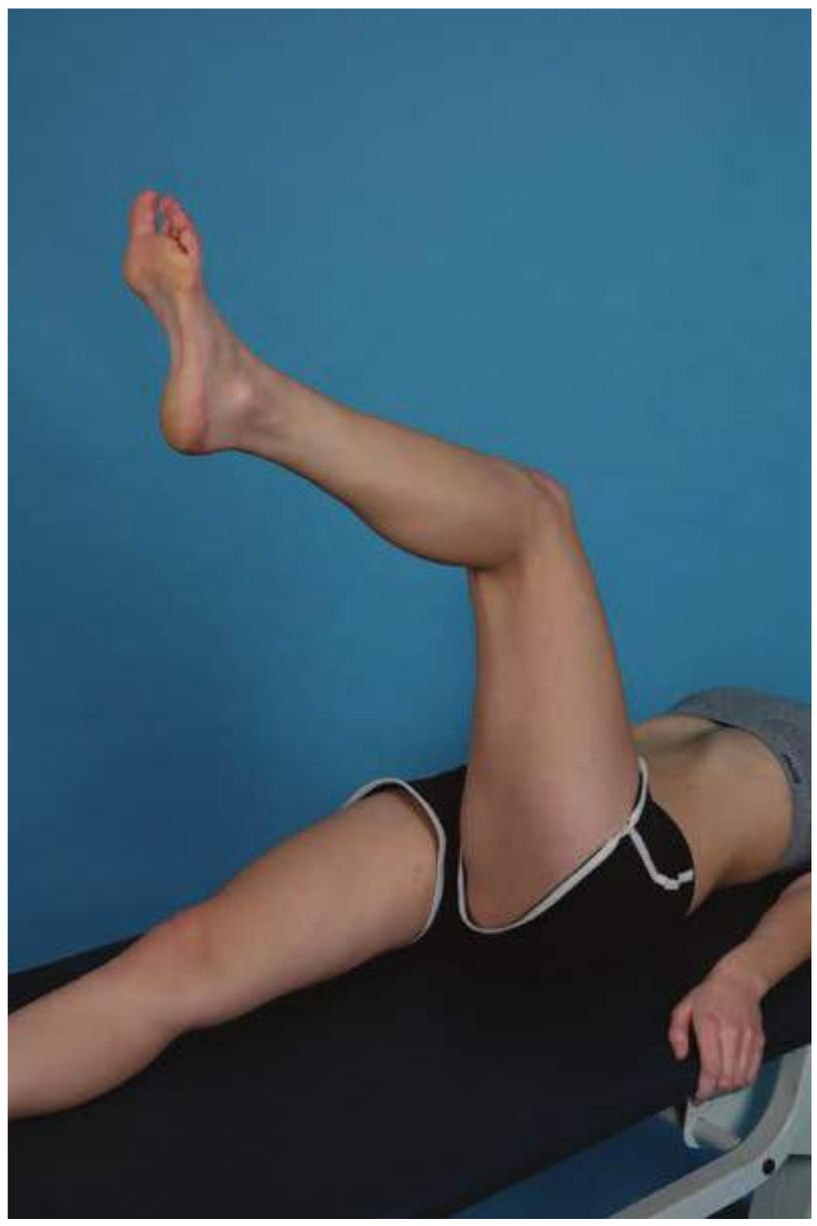

FIGURE 28-16 Single knee to chest.

FIGURE 28-17 Prone lying.

6. Prone lying with passive knee flexion applied by the clinician (Fig. 28-18). This is a confirmatory test for the previous position, if it increases the symptoms in patients with spinal lateral recess stenosis, spondylolisthesis, and an extension or a rotation syndrome[346] (see "Intervention Strategies" section).

The results of these tests should provide the clinician with information on the effect that pelvic tilting in a non–weight-bearing position has on the symptoms. If anterior pelvic tilting appears to aggravate the patient's symptoms, initial positions and exercises that promote posterior pelvic tilting are advocated. If posterior pelvic tilting appears to aggravate the patient's symptoms, initial positions and exercises that promote an anterior pelvic tilt are advocated.

Muscle Strength. Optimum control of the spine and pelvis requires a carefully controlled, dynamic system where the strategy of activation of the trunk muscles matches the functional task. Resisted motions of the lumbar spine can be categorized into those that provide valuable information regarding the origin of lumbar pathology (key muscle testing) and those that assess basic strength parameters, such as dynamic and static motor control.[271]

The gross strength of the trunk can also be assessed by applying a resisting force to the patient's upper back during resisted extension and the shoulders during flexion, lateral bending, and rotation.[271] The clinician notes the presence and type of pain produced and the degree of effort exerted.

Key Muscle Testing. The key muscle tests are used as part of the lower quarter scanning examination (see Chapter 4), because they examine the integrity of the neuromuscular junction and the contractile and inert components of the various muscles.[341] With the isometric tests, the contraction should be held for at least 5 seconds to demonstrate any weakness. If the clinician suspects weakness, the test is repeated two to three times to assess for fatigability. The larger muscle groups, such as the quadriceps, hip extensors, and calf muscles, must be tested by repetitive resistance against a load to stress the muscle–nerve components sufficiently.

Standing up on the Toes (S1–2). The patient raises both heels off the ground (Fig. 28-19). The key muscles tested during this maneuver are the plantar flexors. These are difficult muscles to fatigue, so the patient should perform 10 heel raises unilaterally, with the arms supported by the clinician. In addition to observing for fatigability, the clinician should look for Trendelenburg's sign. A positive Trendelenburg's sign occurs when, during unilateral weight bearing, the pelvis drops toward the unsupported limb; this can indicate a number of

FIGURE 28-18 Prone double knee bend.

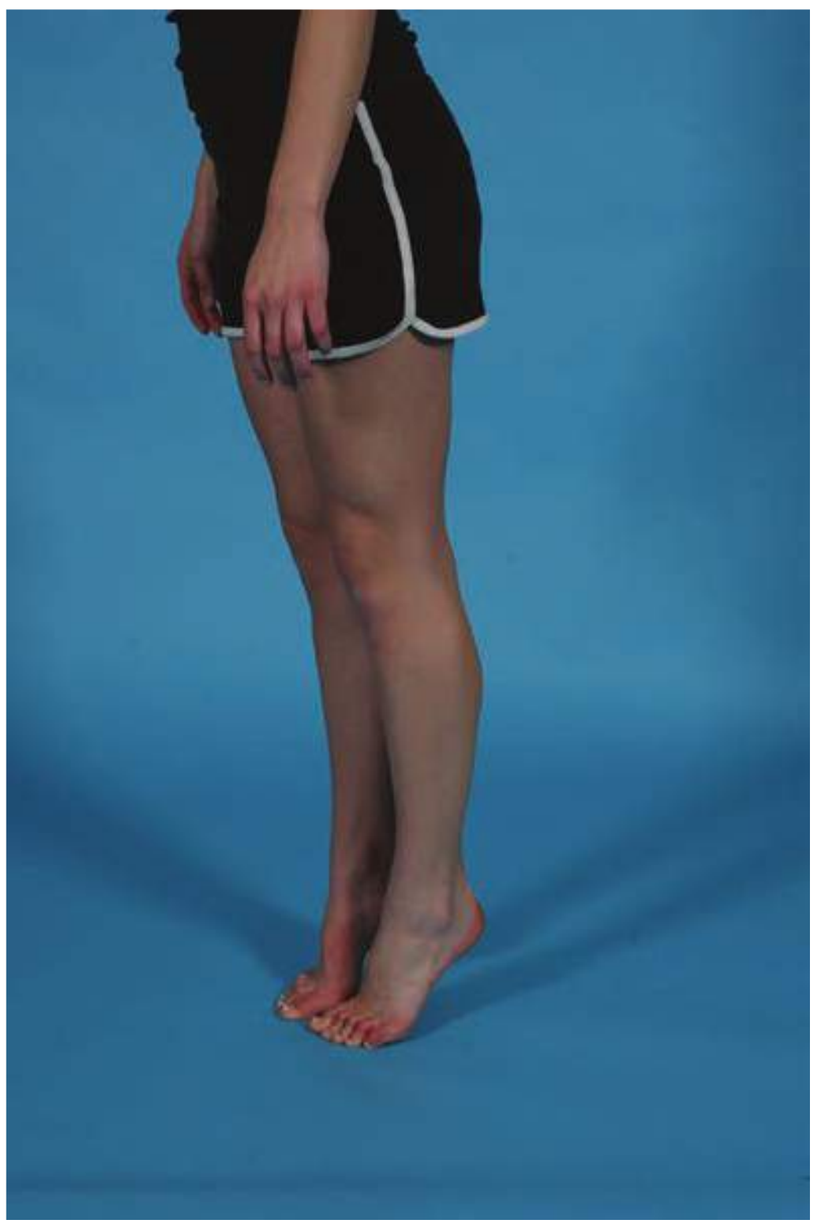

FIGURE 28-19 Standing up on toes.

FIGURE 28-20 Unilateral squat.

FIGURE 28-21 Heel walking.

conditions, including a hip impairment (coxa vara) or a gluteus medius weakness (see Chapter 19).

Unilateral Squat While Supported (L3–4). The patient performs unilateral squats while supported (Fig. 28-20). The key muscles being tested during this maneuver are the quadriceps and hip extensors. Neurologic weakness of the quadriceps (L3–4) is relatively rare and often suggests a nondiskogenic lesion, such as a neoplasm, especially if the weakness is bilateral.[358]

Heel Walking (L4). The patient walks toward, or away from, the clinician while weight bearing through the heels (Fig. 28-21). The key muscles being tested during this maneuver are the dorsiflexors (L4). Approximately 40% of IVD lesions affect this level, about an equal amount as those that affect the L5 root.[29] An IVD protrusion of the L4–5 disk can irritate the fourth root, the fifth root, or, with a larger protrusion, both roots. The dorsiflexors can also be tested in supine (Fig. 28-22).

Hip Flexion (L1–2). With palsy, the patient is unable to raise the thigh off the table. Palsy at this level should always serve as a red flag for the clinician because IVD protrusions at this level are rare, but this is a common site for metastasis.[367] Painful weakness of hip flexion may indicate the presence of a fractured transverse process, metastatic invasion, acute spondylolisthesis, acute segmental articular dysfunction, a major contractile lesion of the hip flexors (rare), or a hip joint pathology. The patient's hip is actively raised off the treatment table to approximately 30–40 degrees of flexion. The clinician then applies a resisted force proximal to the knee into hip extension (Fig. 28-23), while ensuring that the heel of the patient's foot is not contacting the examining table. Both sides are tested for comparison.

Knee Extension (L3–4). The clinician positions the patient's knee in 25–35 degrees of flexion and then applies a resisted flexion force at the middistal shaft of the tibia (Fig. 28-24). Both sides are tested for comparison. Alternately, knee extension can

FIGURE 28-22 Key muscle testing of the dorsiflexors with the patient supine.

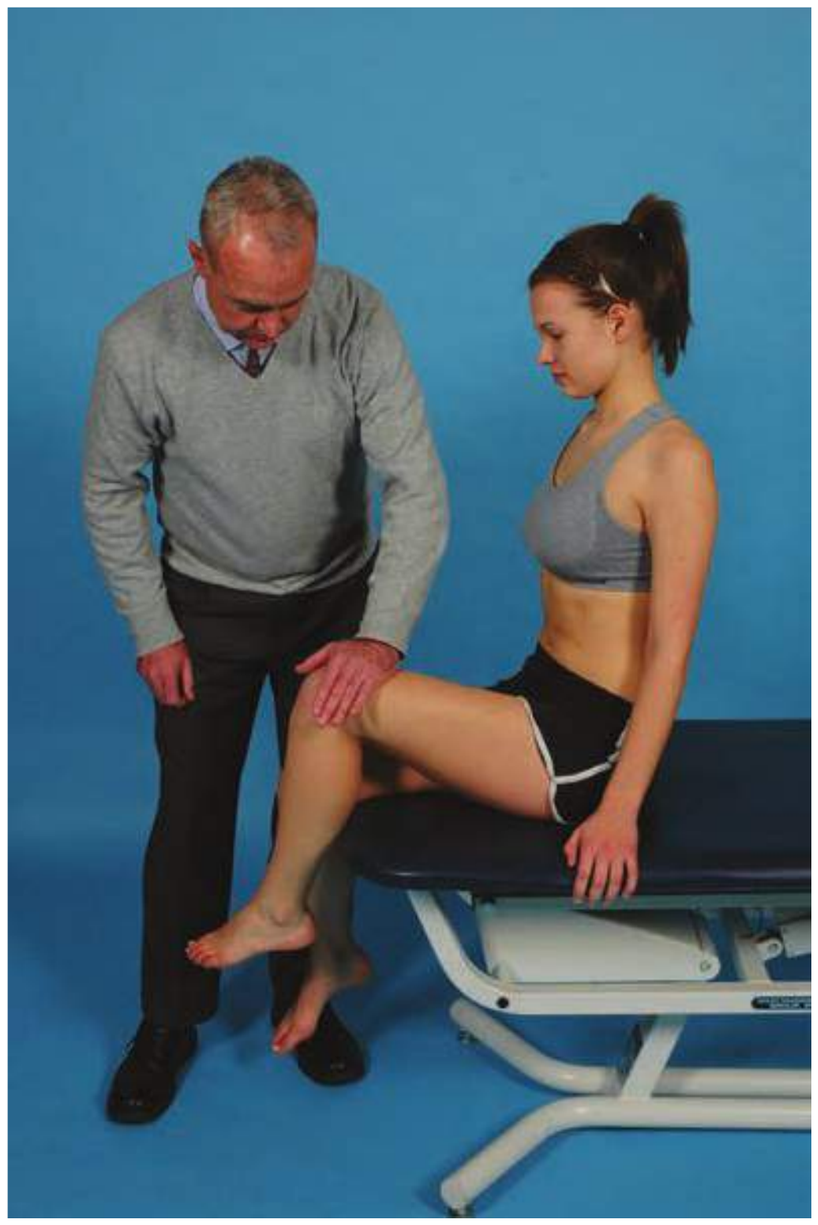

FIGURE 28-23 Resisted hip flexion.

be tested with the patient prone. The patient's leg is positioned in approximately 120 degrees of knee flexion, taking care to do this passively. The clinician rests the superior aspect of his or her shoulder against the posterior aspect of the patient's ankle and grips the edges of the examining table. A force to flex the patient's knee is applied while the patient resists. Both sides are tested for comparison.

FIGURE 28-24 Resisted knee extension.

FIGURE 28-25 Resisted hip extension with knee flexed.

Hip Extension (L5–S1). The patient's knee is flexed to 90 degrees, and his or her thigh is lifted slightly off the examining table by the clinician while the other leg is stabilized. A downward force is applied to the patient's posterior thigh (Fig. 28-25) while the clinician ensures that the patient's thigh is not in contact with the table. Both sides are tested for comparison.

Knee Flexion (S1–2). The patient's knee is flexed to 70 degrees, and an extension isometric force is applied just above the ankle (Fig. 28-26). Both sides are tested for comparison.

Great Toe Extension (L5). The patient is asked to hold the big toe in a neutral position. The clinician then applies resistance to the toe (Fig. 28-27) and compares the two sides.

Ankle Eversion (L5–S1). The patient is asked to place the feet at 0 degrees of plantar and dorsiflexion relative to the leg. A resisted force is applied by the clinician to move each foot into inversion (Fig. 28-28), and a comparison is made.

Muscle Endurance

Impaired function of trunk muscles is closely related to the pathogenesis of chronic LBP. In addition to muscle strength, trunk muscle function can also be described in terms of endurance and speed. Muscle endurance is the ability to produce work overtime or the ability to sustain the effort. Although there is no gold standard to measure trunk muscle endurance, for methods can be used:

1. Kraus–Weber tests for muscular endurance.[368] The following tests are graded on a pass-fail basis, but partial movements on each test can be scored from 0 to 10:
    1. The patient lies supine with the hands behind the neck, and the clinician stabilizes the feet against the bed. The patient is asked to perform one sit-up.

FIGURE 28-26 Resisted knee flexion.

FIGURE 28-27 Resisted great toe extension.

FIGURE 28-28 Resisted ankle eversion.

2. The patient is in the same position except that the knees are flexed with the ankles close to the buttocks. The patient is asked to perform one sit-up without the feet being stabilized.
3. The patient lies supine with the hands behind the neck and the legs extended. The extended legs are lifted 10 in off the floor, and the position is held for 10 seconds.
4. The patient lies prone with a pillow under the lower abdomen and groin. The clinician holds the patient's feet down. The patient is asked to lift head, shoulders, and chest off the bed and to hold the position for 10 seconds.
5. The patient lies prone with a pillow under the lower abdomen and groin. The clinician holds the patient's chest down. The patient is asked to lift both legs off the bed while keeping both knees extended and to hold the position for 10 seconds.

2. Sorensen test for extensors.[369] The patient is positioned in prone on the edge of the table with the ASIS placed at the end of the tables, with the arms bent across the chest and the hips fully extended (Fig. 28-29A). If necessary, the patient can rest the upper trunk and arms on a chair. To secure the patient, three straps are used (one at the pelvis, one behind the knees, and one at the ankle) with a pillow placed under the tibias, or the patient is stabilized by the clinician. Once the patient is positioned correctly, he or she is asked to perform a concentric contraction of the trunk extensors to place the spine approximately horizontal and to hold this position (Fig. 28-29B). The test is stopped when the patient holds the position for 4 minutes, is no longer able to maintain the horizontal position, becomes too fatigued to continue, or experiences pain.
3. Shirado–Ito lumbar and abdominal tests.[370] For measuring the flexion component of the test, the patient is asked to lie in a supine position and to raise the lower extremities with 90 degrees flexion of the hip and knee joints. For measuring extensor endurance, a small pillow is placed under the lower abdomen to decrease the lumbar lordosis, and the patient is asked to lie in a prone position while holding the sternum off the floor. During both procedures, subjects are asked to maintain maximum flexion of the cervical spine, with pelvic stabilization through gluteal muscle contraction. These cervical and pelvic alignments have been found to be the most optimal posture not only for decreasing the lumbar lordosis but also for activating the trunk flexors and extensors most effectively.[370]

Muscle Power and Endurance

The clinician assesses the performance of the trunk flexors, trunk extensors, lateral abdominals, transversus abdominis, hip abductors, and hip extensors, with an appropriate patient in the following manner:[11]

Trunk flexors. The patient is positioned in supine, and the clinician elevates both of the patient's fully extended legs to the point at which the sacrum begins to rise off the table. The patient is instructed to maintain contact with the low back with the table while slowly lowering the extended legs to the table without assistance. The clinician observes and measures

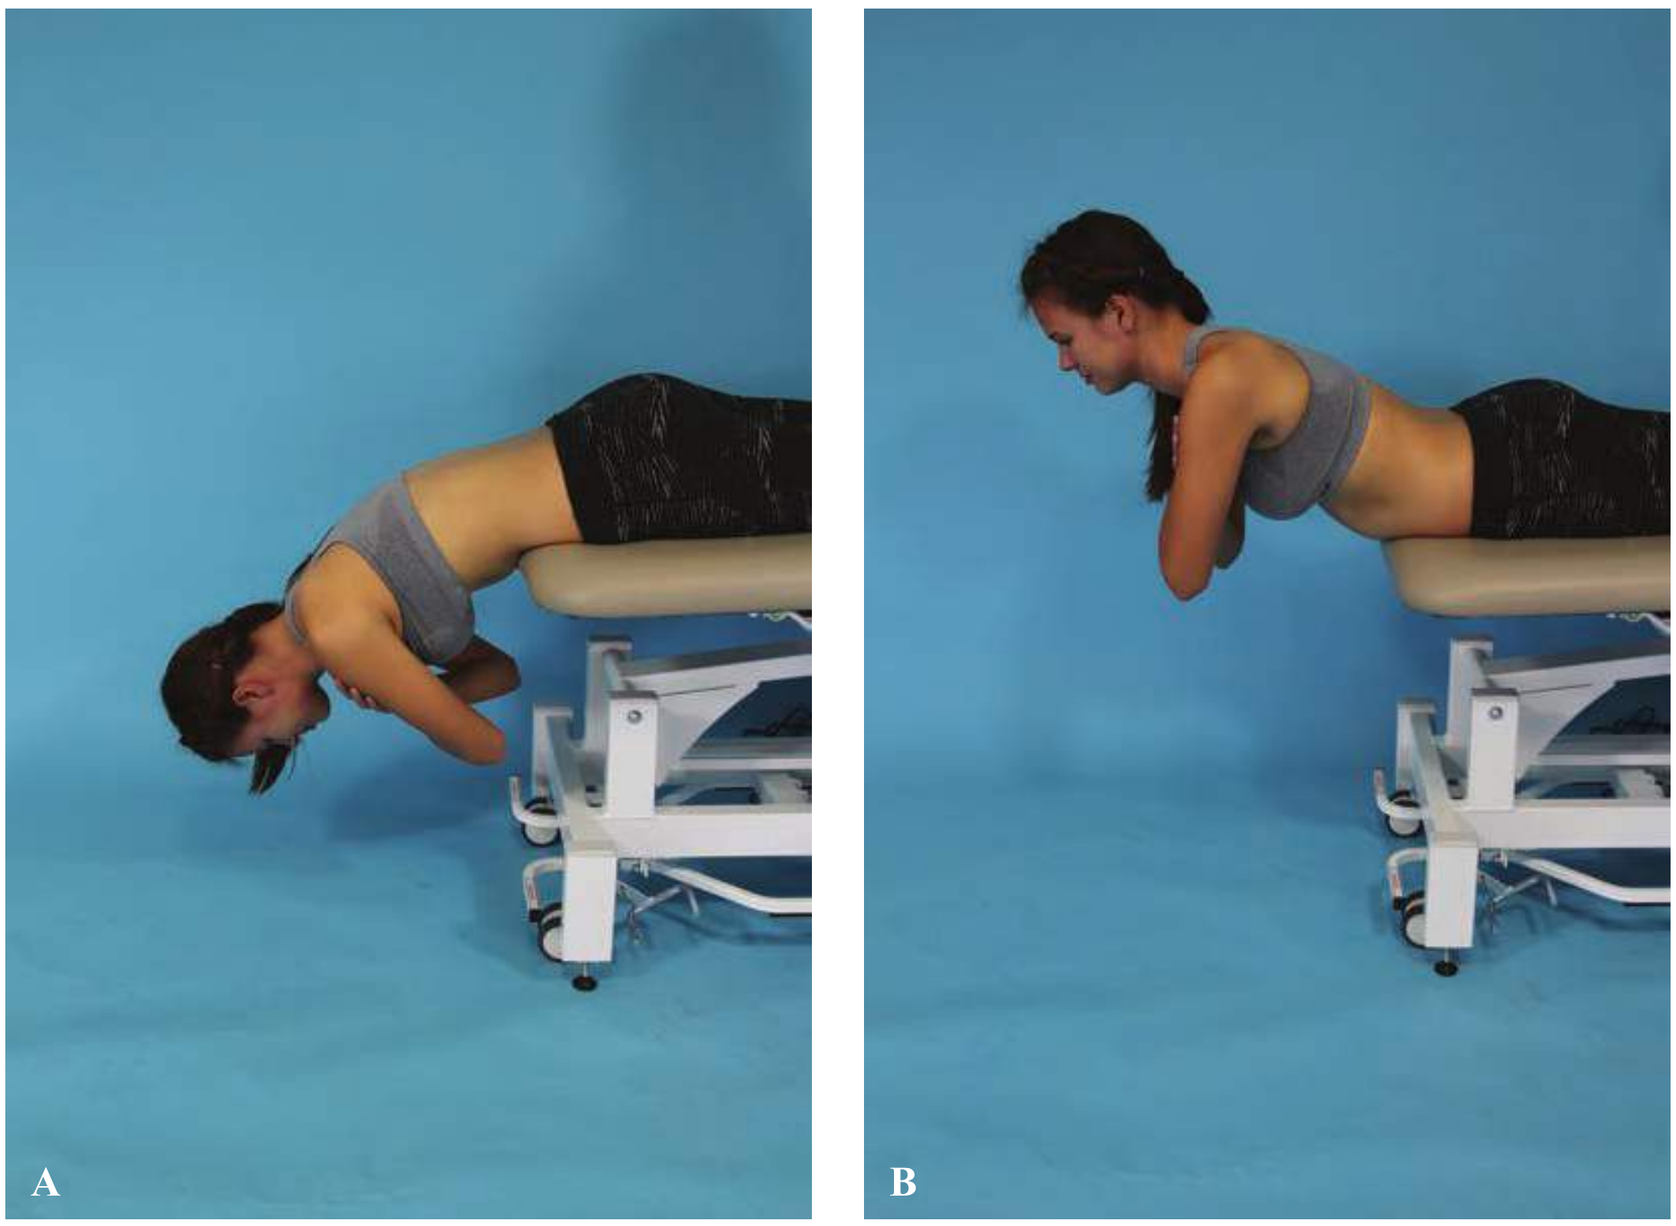

FIGURE 28-29 Sorensen test for extensors. A: Start position. B: End position.

when the lower back loses contact with the tabletop due to an anterior pelvic tilt. T is test has demonstrated discriminative properties in identifying patients with chronic LBP.[371,372] If patients demonstrate anterior pelvic tilt with hip flexion greater than 50 degrees in males and 60 degrees in females, they are more likely to have chronic LBP.[373]

Trunk extensors. T e patient is positioned in prone, with the hands behind the back or by the sides. T e patient is instructed to extend the lumbar spine and raise the chest off the table to approximately 30 degrees and hold that position. T e test is timed until the patient can no longer hold the position. T is test has been highly correlated with the development and persistence of LBP.[370,374,375] Males who are unable to maintain an isometric hold for 31 seconds (33 seconds for females) are significantly more likely to experience LBP (+LR = 4.05–6.5; –LR = 0.24–0.02) with good reliability (intraclass correlation coefficient [ICC] = 0.89–0.90).[374]

Lateral abdominals. T e patient is positioned in side lying with the hips in neutral, knees flexed to 90 degrees, and resting the upper body on the elbow. T e patient is asked to lift the pelvis off the table and to straighten the curve of the spine without rolling forward or backward. T e position is held and timed until the patient can no longer maintain the position. T is test is been found to be reliable in healthy controls (ICC = 0.97).[376,377]

Transversus abdominis. T e patient is positioned in prone over a pressure biofeedback unit that is inflated to 70 mm Hg. T e patient is instructed to draw in the abdominal wall for 10 seconds without inducing pelvic motion and while breathing normally. T e maximal decrease in pressure is recorded. T is test has been found to be reliable (ICC = 0.58; 95% confidence interval [CI]: 0.28, 0.78).[116,378–380] A 4 mm Hg decrease in pressure is established as normal, whereas the inability to decrease the pressure biofeedback device measure by 2 mm Hg is associated with the incidence of LBP.[116,381]

Hip abductors. T e patient is positioned in side lying with both legs fully extended, in neutral rotation and a relaxed arm position, with the top upper extremity resting on the rib cage and hand on the abdomen.[382] T e patient is instructed to keep the leg extended and to raise the top thigh and leg toward the ceiling, keeping the limb in line with the body. Patients are graded on the quality of movement. T is test has demonstrated discriminative ability to predict patients who will develop pain with standing (+LR = 2.68–4.59).[382,383]

Hip extensors. T e patient is positioned in supine with the knees flexed to 90 degrees and the soles of the feet on the table. T e patient is instructed to perform a bridge—raise the pelvis off the table to a point where the shoulders, hips, and knees are in a straight line. T e position is held and timed until the position can no longer be maintained. T is test has demonstrated good reliability (ICC = 0.84).[384] T e mean duration of hold for patients with LBP is 76.7 seconds compared to 172.9 seconds in persons without LBP.[384]

Muscle Stretch Reflexes

T e reflexes should be assessed and graded accordingly, with any differences between the two sides noted. T e tendon should be struck directly once the patient's muscles and tendons are relaxed.

Patellar Reflex (L3). T e patient is positioned sitting, with the legs hanging freely. Alternatively, both knees can be supported in flexion, with the patient placed in supine (Fig. 28-30).

FIGURE 28-30 Patellar reflex.

Hamstring Reflex (Semimembranosus: L5, S1; and Biceps Femoris: S1–2). The patient is positioned prone, with the knee flexed and the foot resting on a pillow. The clinician places a thumb over the appropriate tendon and taps the thumbnail with the reflex hammer to elicit the reflex.

Achilles Reflex (S1–2). The patient is positioned so that the ankle is slightly dorsiflexed with passive overpressure (Fig. 28-31).

Pathologic Reflexes

Pathologic reflexes occur in the presence of motor cortex, brain stem, or corticospinal tract lesions (upper motor neuron [UMN] lesions), wherein the motor response to a sensory stimulus is not modulated. The following pathologic reflexes are described in Chapter 3:

- Babinski;
- Clonus;
- Oppenheim.

Sensory Testing

A thorough evaluation of the sensory system is quite an involved process, due to the number of ascending pathways carrying information to the brain.[271] The clinician checks the dermatome patterns of the nerve roots, as well as the peripheral sensory distribution of the peripheral nerves (see Chapter 3). Dermatomes vary considerably among individuals.

FIGURE 28-31 Achilles reflex.

Superficial Reflexes

There are a number of reflexes that occur in response to stimulation of the skin, known as the superficial reflexes. Three of these, the cremasteric (L1–2), Geigel (L1–2), and anal (S2–5) are pertinent to nerves exiting the lumbar spine.[271] Performance of these superficial reflex tests involves either stroking or pricking the skin of the upper inner thigh (cremasteric and Geigel) or perianal tissue and noting the presence of muscle contraction by the cremasteric (elevation of the testicles), iliopuepartal (elevation of the clitoral prepuce), or external sphincter muscles (also known as anal wink), respectively. It is important to remember that without correlation from the history, and physical examination findings, the absence of a superficial reflex may not ultimately be clinically significant.

Neurodynamic Mobility

The neurodynamic mobility tests that help confirm a lumbar disk herniation include the straight leg raise (SLR), bilateral SLR, crossed SLR sign, slump test, prone knee bend (femoral nerve stretch), and bowstring tests, which are described in Chapter 11.

The lower the angle of a positive SLR test, the more specific the test becomes and the larger the disk protrusion found at surgery.[224,385] A limited SLR at 60 degrees is moderately sensitive for herniated lumbar disks but nonspecific, because limitation often is observed in the absence of disk herniations.[224,386,387] Crossed SLR is less sensitive but highly specific.[386–388] Thus, the crossed SLR test suggests concordance with the diagnosis, whereas ipsilateral SLR is more effective in ruling out the diagnosis.

The femoral nerve stretch test (see Chapter 11) is probably the single best screening test to evaluate for a high lumbar radiculopathy. This test has been shown to be positive in 84–95% of patients with high lumbar disks,[157,389,390] although the test may be falsely positive in the presence of an adaptively shortened iliopsoas or rectus femoris or any pathology in or about the hip joint, sacroiliac joint, and lumbar spine.

Differing Philosophies

The next stage in the examination process depends on the clinician's background. Clinicians who are heavily influenced by the muscle energy techniques of the osteopaths use position testing to determine the segment on which to focus. Other clinicians omit the position tests and proceed to the combined motion and passive physiologic tests.

Position Testing. Position testing in the lumbar spine is an osteopathic technique used to determine the level and type of zygapophyseal joint dysfunction.[98,329,332,391–393] Position testing is performed with the patient in three positions: neutral (Fig. 28-32), flexion (Fig. 28-33), and extension (Fig. 28-34). The transverse processes are then layer palpated (Fig. 28-35). The findings and possible causes for the position testing are outlined in Tables 28-12 and 28-13.

Passive Physiologic Intervertebral Mobility Tests. The passive physiologic intervertebral mobility (PPIVM) tests are most effectively carried out if the combined motion tests locate a hypomobility, or if the position tests are negative, rather than as the entry tests for the lumbar spine.[394,395] Judgments

FIGURE 28-32 Position testing in neutral.

FIGURE 28-34 Position testing in extension.

of stiffness made by experienced physical therapists examining patients in their own clinics have been found to have low reliability[396] for ordered scales,[396] with an ICC of 0.25 in patient studies[397] and kappa coefficient showing poor to minimal agreement (k = –0.2–0.26).[343] Reliability for the presence of any hypomobility or hypermobility during intervertebral motion testing demonstrated moderate to good agreement (k = 0.38–0.48).[398] Validity has been established with correlation of radiographic lumbar segmental instability[399] and with response to treatment.[398]

The passive physiologic movement tests are performed into

- flexion;
- extension;
- rotation;
- side bending.

The adjacent spinous processes of the segment are palpated simultaneously, and movement between them is assessed as the segment is passively taken through its physiologic range.

The test is used for acute and subacute patients who have pain in the cardinal motion planes. For these tests, the patient is in the side-lying position, facing the clinician. The clinician may locate the patient's lumbosacral junction using one of the following methods:

- by locating the L5 spinous process and then moving inferiorly;
- by locating the PSIS and moving superiorly and medially; and
- by locating the spinous process of T12 and counting down to the correct level using the spinous processes.

Once located, the neutral position of the spine for flexion and extension is found by palpating the L5 spinous process and alternatively flexing and extending the hips until it is felt to rock around the flexion and extension point.

Flexion. The patient is close to the clinician, with the underneath leg slightly flexed at the hip and knee. A small pillow or roll can be placed under the patient's waist to maintain the lumbar spine in a neutral position with respect to side bending. The test can be performed by flexing one or both of the patient's legs, but it is generally easier to use one leg. The clinician, facing the patient, palpates between two adjacent lumbar spinous processes in the interspinous space (Fig. 28-36) with the cranial hand, while the other hand grasps the patient's lower legs (Fig. 28-37).

The patient's lower extremities are moved into a combination of hip and lumbar flexion and returned to neutral by the

FIGURE 28-33 Position testing in flexion.

FIGURE 28-35 Layer palpation of the transverse processes. May also be used for P-A pressures.

TABLE 28-12 Causes and Findings for a Flexed Rotated Side Bent Right

Causes of an FRSR	Associated Findings
Isolated left joint extension	PPIVM and PPAIVM tests in hypomobility (FRSR) left extension quadrant are reduced
Tight left flexor muscles (FRSR)	PPIVM test in left extension quadrant is decreased; PAIVM test is normal
Arthrosis or arthritis of left joint in capsular pattern (ERSL < FRSR)	PPIVM and PPAIVM tests in right flexion quadrant are more reduced than in left extension quadrant
Fibrosis of left joint (ERSL = FRSR)	PPIVM and PPAIVM tests are equally reduced in right flexion and left extension quadrants
Left posterolateral disk protrusion (ERSR < FRSR)	PPIVM tests in left extension quadrant are reduced with springy end-feel; both flexion quadrants are normal

ERSL, extended rotated side bent left; ERSR, extended rotated side bent right; FRSR, flexed rotated side bent right; PPAIVM, passive physiologic accessory intervertebral movement; PPIVM, passive physiologic intervertebral mobility.

clinician, as the motion between segments is palpated. Using this general technique, the clinician works up and down the lumbar spine, getting a sense of the overall motion available.

Although there is a high degree of variability in patients, the segmental motion should be felt to decrease from L5 to L1.[60] A generalized hypermobility demonstrates more motion in all of the segments, whereas an isolated hypermobile segment

FIGURE 28-36 Intersegmental palpation.

demonstrates more motion at only that level. Each segment is checked sequentially while moving the lumbar spine passively from neutral to full flexion.

For the mid and upper lumbar segments, this technique can be modified for the larger patient by performing it with the patient sitting up.

Extension. Although flexion and extension can be tested together, it is more accurate to assess them separately. T e patient is positioned as for flexion testing but is oriented diagonally on the bed so that the pelvis is close to the edge, and the shoulder further from the edge. A small pillow or roll

TABLE 28-13 Causes and Findings of an Extended Rotated Side Bent Lef

Causes of an ERSL[a]	Associated Findings
Isolated left joint flexion hypomobility (ERSL); tight left extensor muscles (ERSL)	PPIVM and PPAIVM tests in right flexion quadrant are reduced; PPIVM test in right flexion quadrant is decreased; PPAIVM is normal
Arthrosis or arthritis of left joint in capsular pattern (ERSL < FRSR)	PPIVM and PPAIVM tests are equally reduced in right flexion and left flexion quadrants
Fibrosis left joint (ERSL = FRSR)	PPIVM and PPAIVM tests are equally reduced in right and left flexion quadrants
Right posterolateral disk protrusion (ERSL < FRSL)	PPIVM tests in right extension quadrant are reduced with springy end-feel; both flexion quadrants appear normal

ERSL, extended rotated side bent left; FRSL, flexed rotated side bent left; FRSR, flexed rotated side bent right; PPAIVM, passive physiologic accessory intervertebral movement; PPIVM, passive physiologic intervertebral mobility.

[a] An ERSR would have the same causes and findings, but on the opposite side.

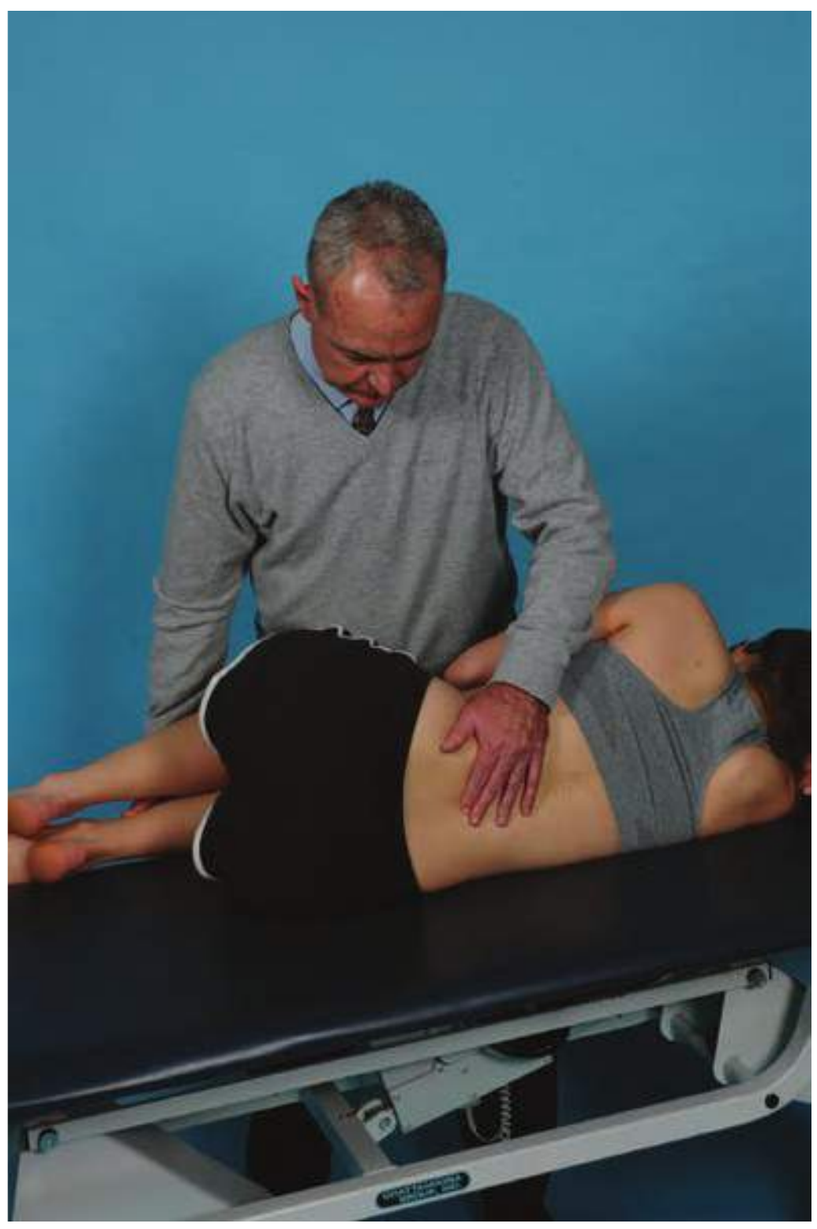

FIGURE 28-37 Passive mobility testing—flexion.

FIGURE 28-38 Passive mobility testing—extension.

can be placed under the patient's waist to maintain the lumbar spine in a neutral position with respect to side bending. The clinician locates two adjacent spinous processes with his or her cranial hand while the caudal arm flexes the patient's knees as much as possible before extending the patient's hips (Fig. 28-38). As the patient's knees move off the table, the clinician supports them on his or her thighs. When the patient's legs are on the table, the clinician's caudal arm is used to produce the hip and the lumbar extension. The pelvis motion is felt, and the spine is returned to its neutral position each time.

Side Bending. The patient is placed in the side-lying position, with the knees and hips flexed, the thighs supported on the table and the lower legs off the table. The lumbar spine should be in a neutral position in relation to flexion and extension. The clinician, facing the patient, places his or her cranial arm between the patient's arm and body and palpates the interspinous spaces, while the caudal hand grasps under the patient's body (Fig. 28-39). As the patient's trunk is lifted toward the ceiling, the superior spinous process should be felt to move away from the table, as the lumbar spine is side bent toward the table. The opposite direction of side bend is tested with the patient side-lying on the opposite side. The technique can also be performed using the patient's legs with the direction of the leg lift representing the direction of the side bending. For example, with the patient in the right side-lying position, right side bending (and left rotation) is introduced by lowering the feet and ankles off the table. The procedure is repeated for the other side, and the two sides are compared.

Rotation. The patient is positioned as described for extension testing in spinal neutral, with both knees being just off the table. A small pillow or roll can be placed under the patient's waist to maintain the lumbar spine in a neutral posi-

FIGURE 28-39 Passive mobility testing—side bending.

tion. The interspinous spaces are palpated with the cranial hand, which is placed along the lower thoracic spine, with a reinforced index finger resting against adjacent spinous processes from underneath (Fig. 28-40).

The patient's pelvis is stabilized by the caudal hand, while the patient's thorax is rotated toward and away from the clinician, using the cranial hand. As the patient's thorax is rotated away, the spinous process of the upper segment should be felt to rotate toward the table, compared with the spinous process of the lower segment.

The spine is returned to neutral each time, and the clinician progresses up the spine. The process is repeated with the patient side lying on the opposite side.

Unfortunately, the PPIVM tests do not completely exclude such intersegmental impairments as minor end-range asymmetric hypo- or hypermobilities, because the application of side bending or rotation in neutral does not fully flex or extend the zygapophyseal joints, nor is it possible to fully flex or extend both zygapophyseal joints simultaneously. In order to completely flex a particular joint, the opposite joint has to move out of the fully flexed position by using side bending and allowing the increased superior glide of the superior zygapophyseal joint on the opposite joint.

Passive Physiologic Accessory Intervertebral Mobility Tests. The passive physiologic accessory intervertebral mobility (PPAIVM) tests investigate the degree of linear or

FIGURE 28-40 Passive mobility testing—rotation.

accessory glide that a joint possesses and are used on segmental levels where there is a possible hypomobility, to help determine if the motion restriction is articular, periarticular, or myofascial in origin. In other words, they assess the amount of joint motion, as well as the quality of the end-feel. The motion is assessed in relation to the patient's body type, and age and the normal range for that segment and the end-feel is assessed for pain, spasm or hypertonicity, or resistance to motion.

Several techniques have been proposed to assess the segmental mobility of the T10–L5 segments, including P-A pressure techniques (see later discussion). The PPAIVM techniques outlined here are used to confirm the findings of the PPIVM tests, by testing the joint glides of that segmental level, to confirm or refute whether a hypo- or hypermobility exists. Spinal locking techniques may be used to help localize these techniques to a specific level, or to a specific side of the segment. Descriptions of the symmetric techniques follow.

A pillow or towel roll should be placed under the lumbar spine of the patient if side bending of the lumbar spine appears to be occurring when the patient is placed in the side-lying position.

Flexion. The patient is in the side-lying position, close to the edge of the bed, with the spine supported in the neutral position, the thighs on the table, and the head resting on a pillow. The clinician faces the patient and locates the suspected segment using palpation. The superior segment is stabilized using the cranial hand (see Fig. 28-41). The clinician now flexes the patient's lumbar spine, using the patient's legs, as in the PPIVM test, until motion is felt at the superior spinous process of the monitored segment.

Using the index and middle fingers of the caudal hand, the clinician straddles the transverse processes of the inferior segment and pulls the segment inferiorly, using the caudal hand and forearm (Fig. 28-42), thereby indirectly assessing the full superior linear glide of the superior segment. The quality and quantity of the joint glide are assessed.

Extension. The patient and clinician are positioned as in the PPIVM test, with the patient being positioned diagonally on the bed, hips forward, knees well flexed, and the head resting on a pillow.

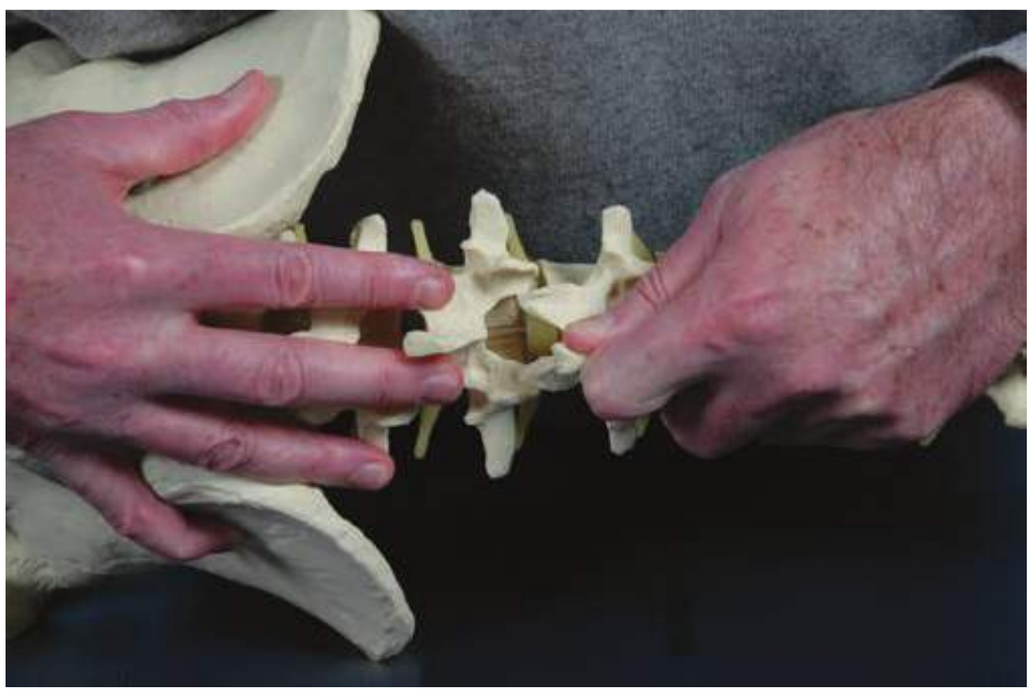

FIGURE 28-41 Passive articular mobility testing for flexion showing stabilization.

FIGURE 28-42 Passive articular mobility testing for flexion.

Having located the suspected level, the clinician extends the patient's spine to that level by pushing the patient's legs across the table until the monitoring finger detects motion at the superior spinous process. The superior spinous process of the segment is pinched (see Fig. 28-43) and the joint complex is passively taken into full extension by straddling the transverse processes, as for the flexion technique, and pushing the caudal vertebra anteriorly (see Fig. 28-44). At the end of the available range, the transverse processes of the inferior segment are glided in a cranial direction to test the full linear glide. The quality and quantity of the joint glide are assessed.

Side Bending. The patient and clinician are positioned as in the PPIVM test, with the patient's hips forward, knees well flexed, and the head resting on a pillow. The side on which the patient lies is determined by the intent of the technique.

- To test the ability of the segment to side bend ipsilaterally (close), the patient lies on the side to be tested.
- To test the ability of the segment to side bend contralaterally (open), the patient lies with the side to be tested uppermost.

Having located the suspected level, the clinician extends or flexes the patient's spine to that level by pushing the patient's legs across the table until the monitoring finger detects motion at the superior spinous process.

FIGURE 28-43 Passive articular mobility testing for extension showing stabilization.

FIGURE 28-44 Passive articular mobility testing for extension.

The clinician places the axilla of his or her caudal arm over the iliac crest of the patient, while the index and middle fingers of the hand are placed over the spinous processes of the inferior vertebra (Fig. 28-39). The clinician firmly squeezes the patient's pelvis and upper thigh with the caudal arm and applies a force in an inferior direction toward the patient's feet, while the middle finger of the caudal hand pushes the spinous process superiorly.

The quality and quantity of the joint glide are assessed and compared with the other side.

Rotation. The patient is positioned as in the PPIVM test. A small pillow or roll can be placed under the patient's waist to maintain the lumbar spine in a neutral position. The patient's pelvis and the inferior aspect of the caudal spinous process are fixed using the caudal arm and hand, respectively (Fig. 28-45). The thumb of the other hand is placed on the superior aspect of the cranial spinous process.

As the patient's thorax is rotated away, the spinous process of the upper segment should be felt to rotate toward the table, compared with the spinous process of the lower segment. The quality and quantity of the joint glide are assessed. The spine is returned to neutral each time, and the clinician progresses up the spine. The process is repeated with the patient side lying on the opposite side.

Functional Assessment Tools

Disability and the patient's ability to function may actually be more significant to health care costs than pain alone.[400]

FIGURE 28-45 Passive articular mobility testing for rotation.

Several instruments have been produced in the past 30 years, which can provide reliable and valid methods to quantify a patient's functional status.[401]

Overall, no instrument is probably used more often for assessment of the low back than the Oswestry Low Back Disability Questionnaire (OLBDQ),[402] which has been widely researched and validated by investigators of spinal disorders (see Chapter 5).

The Roland–Morris Disability Questionnaire (RDQ)[403] (Table 28-14) is a health status measure, designed to be completed by patients to assess physical disability due to LBP. The RDQ was derived from the Sickness Impact Profile (SIP), which is a 136-item health status measure covering all aspects of physical and mental function.[404] Twenty-four items were

TABLE 28-14 The Roland–Morris Disability Questionnaire

When your back hurts, you may find it difficult to do some things you normally do

This list contains sentences that people have used to describe themselves when they have back pain

When you read them, you may find that some stand out because they describe you today

As you read the list, think of yourself today. When you read a sentence that describes you today, put a tick against it. If the sentence does not describe you, then leave the space blank and go on to the next one

Remember, only tick the sentence if you are sure it describes you today

- □ I stay at home most of the time because of my back
- □ I change position frequently to try and get my back comfortable
- □ I walk more slowly than usual because of my back
- □ Because of my back I am not doing any of the jobs that I usually do around the house
- □ Because of my back, I use a handrail to get upstairs
- □ Because of my back, I lie down to rest more often
- □ Because of my back, I have to hold on to something to get out of an easy chair
- □ Because of my back, I try to get other people to do things for me
- □ I get dressed more slowly than usual because of my back
- □ I only stand for short periods of time because of my back
- □ Because of my back, I try not to bend or kneel down
- □ I find it difficult to get out of a chair because of my back
- □ My back is painful almost all the time
- □ I find it difficult to turn over in bed because of my back
- □ My appetite is not very good because of my back pain
- □ I have trouble putting on my socks (or stockings) because of the pain in my back
- □ I only walk short distances because of my back
- □ I sleep less well on my back
- □ Because of my back pain, I get dressed with help from someone else
- □ I sit down for most of the day because of my back
- □ I avoid heavy jobs around the house because of my back
- □ Because of my back pain, I am more irritable and bad tempered with people than usual
- □ Because of my back, I go upstairs more slowly than usual
- □ I stay in bed most of the time because of my back

selected from the SIP, and each item was qualified with the phrase "because of my back pain" to distinguish back pain disability from disability resulting from other causes—a distinction that patients are, in general, able to make without difficulty.[404,405]

Patients are asked to place a check mark beside a statement if it applies to them that day, and the score is calculated by adding up the number of items checked. Scores, therefore, range from 0 (no disability) to 24 (maximum disability). RDQ scores have been found to correlate well with other measures of physical function, including the physical subscales of 36-item Short Form Health Survey (SF-36), the SIP, and the OLBDQ.[404]

The Physical Impairment Index (PII), designed by Waddell et al.,[231] is a series of seven tests, each scored positive or negative based on published cutoff values (Table 28-15) that tend to provide a measurement of physical impairment in patients with LBP. The final score of the PII ranges between zero and seven, with higher numbers indicating greater levels of impairment. Fritz and Piva[406] in a study of 78 patients with acute (<3 weeks duration) LBP found the PII to have a high interrater reliability (ICC = 0.89), and its validity was generally supported by the pattern of correlations. The minimum detectable change on the index was approximately one point.

Fear Avoidance Beliefs Questionnaire (FABQ)[407] (see Chapter 4) was developed, based on theories of fear and avoidance behavior, and focused specifically on patients' beliefs about how physical activity and work affected their LBP. Each item of the FABQ is scored 0–6, with higher numbers indicating increased levels of fear avoidance beliefs. Two subscales are contained within the FABQ: a seven-item work subscale (score range 0–42) and a four-item physical activity subscale (score range 0–24). The subscales of the FABQ have shown good reliability,[408] and previous studies have found the FABQ work subscale to be associated with current and future disability and work loss in patients with chronic[409–411] and acute[412–415] LBP.

Pain catastrophizing is a negative belief that the experienced pain will inevitably result in the worst possible outcome.[416] Pain catastrophizing is believed to be a multidimensional construct comprising rumination, helplessness, and pessimism.[416] Pain catastrophizing can be measured using the Pain Catastrophizing Scale (PCS) which is a 13 item scale with a potential range of 0–52 that assesses the extent of catastrophic cognitions a patient experiences while in pain. Higher scores indicate higher levels of pain catastrophizing. The PCS assesses three independent dimensions of pain catastrophizing: rumination (items 8–11: ruminating thoughts, worrying, inability to inhibit pain-related thoughts), magnification (item 6, 7, 13: magnification of the unpleasantness of pain situations and expectancies for negative outcomes), and helplessness (items 1–5, 12: inability to deal with painful situations).[417–419]

Special Tests

Centralization. The patient either stands or lies prone depending on the intent of a loaded or unloaded assessment. Multiple directions of repeated end-range lumbar testing are targeted. Movements may include extension, flexion, or side flexion. Movements are generally repeated for 5–20 attempts until a definite centralization or peripheralization of symptoms occurs. Centralization of symptoms is considered a positive finding for diskogenic symptoms. In a study by Donelson et al.,[292] the presence of centralization had a sensitivity of 92% and specificity of 64% (LR+ 2.6; LR− 0.12) as a predictor for symptomatic disks.

The Single-Legged Squat. The single-legged squat (Fig. 28-20) can be used as an indicator of lumbopelvic–hip stability. The test is functional, requires control of the body over a single weight-bearing lower limb and is frequently used clinically to assess hip and trunk muscular coordination and/or control.[420]

Loss of Extension. The patient lies in the prone position. The patient is asked to extend his or her lumbar spine while keeping the pelvis in contact with the treatment table. A positive test for diskogenic symptoms is moderate or major loss of extension. In a study by Laslett et al.[421] using visual observation only found that a loss of extension in predicting symptomatic disks had a sensitivity of 27% and specificity of 87% (LR+ 2.01; LR− 0.84).

Neurodynamic Mobility Testing. The slump, straight-(Well) leg raise, bowstring, double SLR, and prone knee flexion tests are described in Chapter 11. In a population of patients with a new episode of pain radiating below the gluteal fold, the SLR test has demonstrated good reliability (k = 0.68) for identifying pain in a dermatomal distribution and moderate reliability for identifying patients with symptoms for angles below 45 degrees (k = 0.43).[422] For the slump test reported scores were from 0.83 to 0.89 for 6 pairs of physical therapist of varying experience testing 93 patients receiving treatment for low-back and/or leg pain.[423]

Milgram's Test. Milgram's test is as much an assessment of abdominal muscle strength as it is intrathecal irritability.[271] With legs fully extended, the supine patient is asked to raise both feet approximately 2 in off the table and maintain this position for at least 10 seconds and up to 30 seconds (Fig. 28-46). The inability to perform this test due to muscle weakness is not considered a positive finding within the context of this test, but should nevertheless still be charted.[271]

Posteroanterior Pressures. The patient is positioned in prone. P-A pressures, advocated by Maitland,[424] are applied to the spinous, mammillary, and transverse processes of this region. The clinician should keep the elbows extended and utilize the upper trunk to impart the P-A force in a slow and gentle fashion using the index and middle fingers of one hand, while monitoring the paravertebrals with the other hand (see Fig. 28-47).

Although these maneuvers are capable of eliciting pain, restricted movement, or muscle spasm, or a combination, they are fairly nonspecific in determining the exact level involved, or the exact cause of the symptoms, and have been found to have poor interrater reliability in the absence of corroborating clinical data.[397,425] In a single-group repeated-measures interrater reliability study by Hicks et al.[343] to determine the interrater reliability of common clinical examination procedures proposed to identify patients with lumbar segmental instability, a consecutive sample of 63 subjects (38 women,

TABLE 28-15 Physical Impairment Index Along with Scoring Criteria

Test	Performance	Scoring	
		Positive	Negative
Total flexion range of motion	The patient stands erect. The inclinometer is held at T12–L1, and the patient is asked to reach down as far as possible toward the toes, while keeping the knees straight.	Less than 87 degrees	Greater than or equal to 87 degrees
Total extension range of motion	The patient stands erect. The inclinometer is held at T12–L1. The patient is asked to arch backward as far as possible. The clinician may support the patient with one hand on the shoulder for balance.	Less than 18 degrees	Greater than or equal to 18 degrees
Average lateral flexion range of motion	The patient stands erect, with the inclinometer aligned vertically in line with the spinous processes of T9 and T12. The patient is asked to lean straight over to one side as far as possible, with the fingertips reaching straight down the side of the thigh. The clinician may support the patient's shoulder with one hand. The patient repeats the motion to the opposite side. Average lateral flexion is computed.	Less than 24 degrees	Greater than or equal to 24 degrees
Average straight-leg raised range of motion	The patient is supine. In inclinometer is positioned on the tibial crest just below the tibial tubercle. The leg is raised passively by the clinician, whose other hand maintains a knee in extension. The leg is raised slowly to the maximum tolerated straight leg raise (not the onset of pain). The opposite leg is tested in the same manner. Average straight-leg raising computed.	Males: less than 66 degrees Females: less than 71 degrees	Males: greater than or equal to 66 degrees Females: greater than or equal to 71 degrees
Spinal tenderness	The patient is prone with the back muscles relaxed. Palpation is done slowly without sudden pressure. Superficial tenderness to light-skinned pinch is a test first. The patient is asked "is that painful?" Any response other than "no" is a positive. If superficial tenderness is not present, deep tenderness is assessed by placing firm pressure with the ball of the thumb over the spinous processes and interspinous ligaments within 1 cm of the midline from T12 to S2. Again the patient is asked, "is that painful?" Any response other than "no" is a positive test.	Positive superficial or deep spinal tenderness	Negative superficial or deep spinal tenderness
Bilateral active straight-leg raise	The patient is supine with the knees extended. The patient is asked to lift both legs together 6 in off the examining surface and hold that position for 5 s. The clinician should not count aloud or offer encouragement. The patient may not use the hands to lift the legs. If the patient is unable to maintain the lifted position for 5 s, the test is positive.	Positive test	Negative test
Active sit-up	The patient is supine with the knees flexed to 90 degrees and the feet flat. The clinician should hold the patient's feet with one hand. The patient is instructed to reach out with the fingertips to touch (not hold) both knees and hold that position for 5 s. The clinician should not count aloud or offer encouragement. If the patient is unable to maintain the position for 5 s, the test is positive.	Positive test	Negative test

Data from Waddell G, Somerville D, Henderson I, et al. Objective clinical evaluation of physical impairment in chronic low back pain. Spine. 1992;17:617–628; Fritz JM, Piva SR. Physical impairment index: Reliability, validity, and responsiveness in patients with acute low back pain. Spine. 2003;28:1189–1194.

25 men; 81% with previous episodes of LBP) with current LBP was examined by three pairs of raters. The results of the study agreed with other studies, suggesting that segmental mobility testing is not reliable. In fact, in this study, the prone instability test (see later), Beighton–Horan Ligamentous Laxity Scale, and the presence of aberrant motion with trunk ROM demonstrated higher levels of reliability.

CLINICAL PEARL

The Beighton–Horan Ligamentous Laxity Scale[426] measures the following five elements:

- Passive opposition of the thumb to the flexor aspect of the forearm (one point per hand)

FIGURE 28-46 Milgram's test.

- Passive hyperextension of the fifth metacarpal phalangeal joint beyond 90 degrees (one point per hand)
- Hyperextension of the elbows by 15 degrees or more (one point per arm)
- Hyperextension of the knees (one point per leg)
- Forward flexion of the trunk with knees extended and palms flat on floor (one point)
- All elements are added together to give an overall ligamentous laxity score ranging from 0 (tight) to 9 (hyperlax).

As a screening tool, the P-A pressures have their uses and can help detect the presence of excessive motion or spasm. However, caution should be exercised when making clinical decisions related to the assessment of motion at a specific spinal level using P-A accessory motion testing. Consider the following example with the patient positioned prone:

- A P-A pressure is applied simultaneously to both transverse processes of the L3 segment. Biomechanically, this produces a relative extension movement of the L2–3 segment, while producing a flexion movement of the L3–4 segment.
- If the spinous process of L3 is pushed to the right, inducing a left rotation of L3, this produces a relative right rotation of L2 on L3, but a left rotation of L3 on L4.

FIGURE 28-47 P-A pressures.

Anterior Stability Test. The patient is in the side-lying position. To test the lower three segments (L3–5), the patient's hips are placed in approximately 70 degrees of flexion, and the knees are flexed (Fig. 28-48A). This position is to prevent tightening of the posterior lumbar ligaments, particularly the SSL, which could stabilize the lower three segments and produce a false-negative test result.[394] The clinician stands to face the patient, resting his or her thighs against the patient's knees. The upper segments are stabilized using the cranial hand and the other hand over it. The inferior interspinous space is palpated. The clinician pushes with the thighs, through the patient's knees, along the line of the femur (Fig. 28-48B). This is produces a posteriorly directed force to the pelvis, sacrum, and lumbar spine. Any posterior movement of the inferior segment, which is actually a relative anterior movement of the superior segment on the inferior segment, is noted and compared with the next segmental level. There should be little or no movement. To test the upper two segments (L2 and L1), the lumbar spine is flexed by flexing the hips to approximately 100 degrees, and the procedure is repeated. A positive test is one in which there is excessive movement or pain, or both.

Lateral Stability Test. This test does not rely on the objectivity of the end-feel. Instead, an indirect shearing maneuver is used, and the reproduction of pain is considered a positive test.[358,394] The patient lies in the side-lying position facing the clinician, with the lumbar spine positioned in neutral and the hips and knees flexed to approximately 45 degrees. The clinician, using the fleshy part of one forearm, applies a downward pressure on the lateral aspect of the patient's trunk at the level of the L3 transverse process (Fig. 28-49). This is produces a lateral translation of the entire lumbar spine in the direction of the bed. The pressure is applied until an end-feel is detected. The test is repeated with the patient side lying on the opposite side.

Hip Abduction Test.[382] This test was designed to test the patient's ability to maintain correct trunk and pelvic alignment while raising the upper leg from an inherently unstable side-lying position. It was hypothesized that an inability to perform this test might indicate that a patient may develop LBP as a result of the inability to stabilize the spine properly during prolonged standing.

Prone Instability Test.[343] The patient is positioned prone so that the trunk rests on the bed, and their feet rest on the floor, with the hips flexed and the trunk muscles relaxed. The clinician applies a P-A pressure (approximately 4 kg or thumbnail blanching) over the most symptomatic spinous process, and any reproduction of symptoms is noted. The clinician then releases the P-A pressure, and the patient is asked

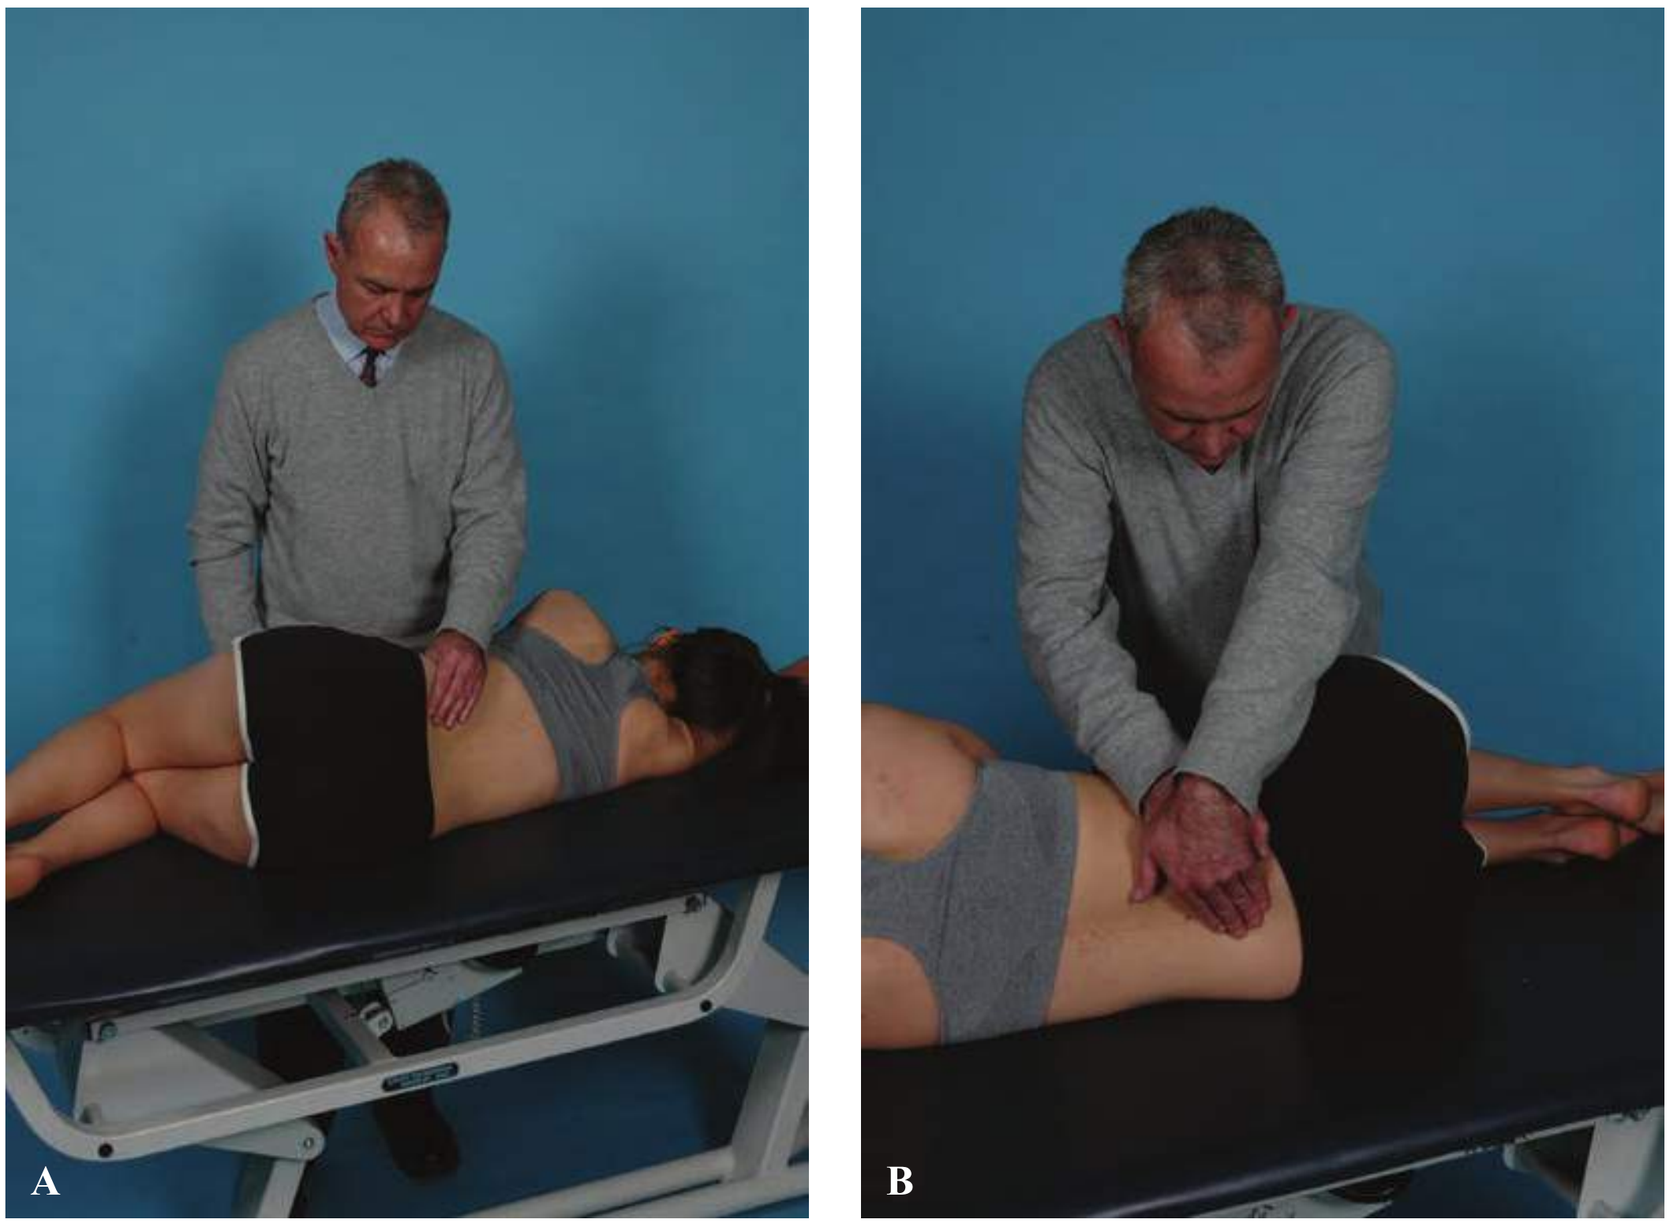

FIGURE 28-48 Anterior stability test. A: Patient position. B: Technique.

to hold onto the sides of the table and to slightly lift his or her feet off the floor (Fig. 28-50). T is maneuver produces a cocontraction of the global abdominal, gluteal, and erector spinae muscles. While the patient maintains their feet off the floor, the clinician reapplies the P-A pressure over the same spinous process level. If a dramatic reduction or the complete elimination of the symptoms compared to the first application of P-A pressure is noted (the muscle activity must be able to effectively stabilize the segment), it is considered a positive prone instability test. T is test has been found to have good to excellent agreement (k = 0.87)[343] for three pairs of physical therapy raters evaluating 63 consecutive subjects currently experiencing LBP and with a previous history of LBP. According to Hicks et al.,[343] patients with LBP, who present with a negative prone instability test, are unlikely to respond to a stabilization exercise program. However, it must be remembered that as an independent test, the Prone Instability Test has limited diagnostic use (+LR = 1.7 [95% CI: 1.1, 2.8]; –LR = 0.48 [95% CI: 0.22, 1.1]);[427] as it is most useful as a component of a cluster of tests to predict response to motor control exercises.[427]

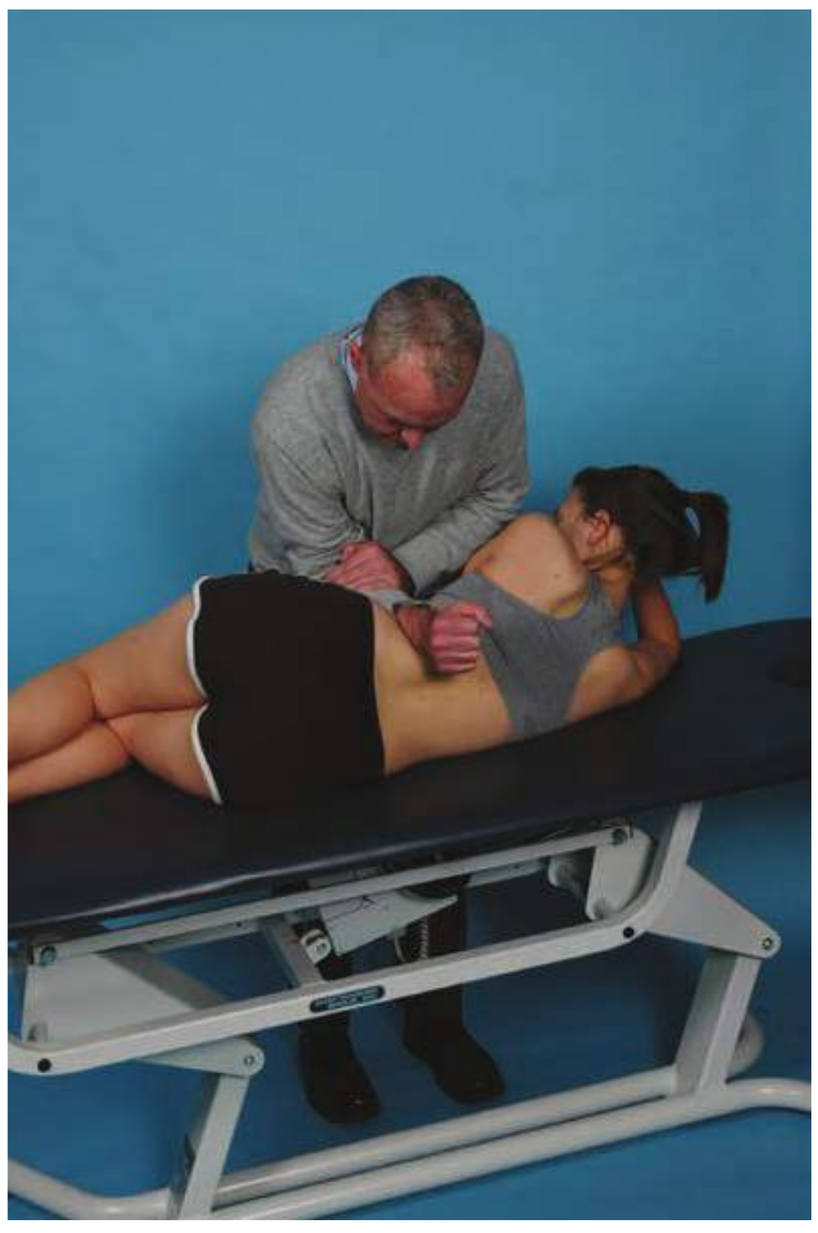

FIGURE 28-49 Lateral stability test.

FIGURE 28-50 Prone instability test.

FIGURE 28-51 Passive lumbar extension test.

Passive lumbar extension test.[428] The passive lumbar extension test is used to help detect lumbar spinal instability. The patient lies in the prone position, with the clinician standing at the foot of the bed. The clinician grasps the patient's lower legs and, while applying a gentle traction force, raises both of the patient's lower extremities concurrently to a height of approximately 30 cm from the bed, while maintaining the knees extended (Fig. 28-51). Pain, apprehension, or a sense of heaviness in the low back are considered positive findings for this test. The test has been shown to have a sensitivity of 84.2% and a specificity of 90.4%.[428] The positive likelihood ratio of the test was 8.84 (95% CI: 4.51–17.33).[428]

CLINICAL PEARL

A 2011 systematic literature review[429] found that the majority of clinical tests routinely employed to diagnose structural lumbar segmental instability demonstrated only limited ability to do so. However, the same study reported that the passive lumbar extension test may be useful in orthopaedic clinical practice to diagnose structural lumbar segmental instability. A more recent study,[430] that looked at the interrater reliability of the passive lumbar extension test, the active SLR test, the lumbar extension load test, and the active hip abduction test concluded that, with the exception of the active hip abduction test, all of the other clinical tests can be considered sufficiently reliable for clinical use in predicting the outcome or suggesting the need for lumbar stabilization exercises.

Imaging Studies

Plain radiography should be limited to patients with clinical findings suggestive of systemic disease or trauma. Guidelines recommend plain radiography for patients with fever, unexplained weight loss, a history of cancer, neurologic deficits, alcohol or injection–drug abuse, an age of more than 50 years, or trauma.[431] A major diagnostic problem with LBP is that many anatomic abnormalities seen on imaging tests, including myelography, CT, and MRI, are common in healthy individuals.[432,433] The high prevalence of these abnormalities in the absence of symptoms suggests that making causal inferences may be hazardous. In the absence of corresponding clinical findings (from the history and physical examination), these anatomic derangements seem to be irrelevant and inconsequential.[434]

Bulging disks viewed on MRI are commonly implicated as the cause of symptoms. However, bulging disks are more common than not after the age of 50 years and often have little, if any, association with symptoms.[434]

Examination Conclusions

Following the examination, a working hypothesis, or diagnosis, can be established based on a summary of all of the findings. For example, the tests and measures can help to determine

- the presence of a medical diagnosis, such as a spinal lateral recess stenosis, ankylosing spondylitis, or an IVD protrusion;
- the presence of nonorganic signs. Inconsistencies occurring during the history and examination, which seem to be lacking in any somatic or organic base, have become known as nonorganic findings (see "Psychogenic Pain" section in Chapter 5). Nonorganic findings do not necessarily imply a nonexistent or fictitious condition. Waddell[435] developed a series of tests designed to elicit nonorganic responses from patients in whom psychosocial factors are suspected (see Chapter 5).

A pathology-based or biomechanical approach to LBP is based on the notion that LBP results from a deviation of the lumbopelvic complex from its normative physiologic and anatomic state and that by identifying a structural fault, and then correcting that fault, will lead to a dissipation of the signs and symptoms. Tables 28-16 to 28-18 summarize the typical findings in a patient with a biomechanical diagnosis, highlighting both the similarities and the differences between each. The difficulty in identifying a pathoanatomic cause for most patients with LBP has prompted efforts to identify alternative methods of subgrouping, or classifying, affected individuals based on clusters of examination findings. In 1995, Delitto et al.[436] published a treatment-based classification system (TBC) (see Chapter 22) which proposed four classifications for patients with higher levels of disability, each with a distinct set of examination findings and an associated intervention strategy thought to optimize outcomes for patients in the category. The information gathered from the physical examination and patient self-reports of pain (pain scale and pain diagram) and disability (modified Oswestry Questionnaire) was used to determine whether the patient's condition would be amenable to physical therapy or whether care from another practitioner would be required. The problem with this classification system was that the clusters of examination

Reduced gross PPIVM, but PPAIVM normal	Reduced gross PPIVM and PPAIVM
Intervention	Intervention
Muscle relaxation techniques, transverse frictions, and stretches	Joint mobilizations at specific level

PPAIVM, passive physiologic accessory intervertebral movement; PPIVM, passive physiologic intervertebral mobility.

TABLE 28-17 Interpretation of Findings: Reduced Movement—Example 2

Pericapsular/Arthritis	Disk Protrusion
Cause	Cause
Degenerative or degradative changes	Cumulative stress
	Low level but prolonged overuse
	Sudden macrotrauma
Findings	Findings
Negative scan	Positive lower quarter scan
Reduced gross PPIVM in all directions except flexion	Key muscle fatigable weakness
Active motion restricted in capsular pattern (decreased extension and equal limitation of rotation and side flexion)	Hyporeflexive deep tendon reflexes
	Sensory changes in dermatomal distribution
	Subjective complaints of radicular pain
PPIVM and PPAIVM findings	PPIVM and PPAIVM findings
Reduced gross PPIVM, but PPAIVM normal	Reduced gross PPIVM and PPAIVM
Intervention	Intervention
Capsular and muscle stretching	Traction
Active exercises and PREs	Active exercises into spinal extension
Anti-inflammatory modalities, if necessary	Positioning
Joint protection techniques	

PPAIVM, passive physiologic accessory intervertebral movement; PPIVM, passive physiologic intervertebral mobility; PRE, progressive resisted exercise.

findings used to make classification decisions and intervention strategies were principally derived from expert opinions and limited available evidence. Although the reliability of clinicians in performing the individual examination items used in the clinical prediction rules has been shown to be fair to good, agreement among clinicians to classify patients with LBP using the TBC system has only been tested in a preliminary manner.[437] In 2006, Fritz et al. published a report in an effort to update this decision-making algorithm. The goal of this RCT study was to test the hypothesis that a patient with LBP, who received interventions matched to the patient's classification would have better outcomes than those receiving unmatched interventions. After completion of the baseline examination, patients were randomized into one of three intervention groups (manipulation, specific exercise, or stabilization) and referred to physical therapy (Table 28-19). In a 2011 study,[438] using patients with acute or subacute (duration less than 90 days) LBP, the authors found that approximately 50% of the participants met the criteria for only one TBC subgroup, 25% of the patients met the criteria for more than one subgroup, and the other 25% of the participants did not meet the criteria for any subgroup.[438] This would tend to indicate that additional refinement is needed to reduce rater disagreement in the TBC decision-making algorithm. In particular, it is necessary to determine which categories are the most difficult to distinguish. This problem was tackled in a study by Henry et al.[439] that found prevalent patterns of disagreement involving the stabilization category: stabilization-manipulation and stabilization-specific exercise.

From a prognosis viewpoint, the failure of a patient to improve with conservative care can be a sign of a serious medical condition or misdiagnosis.[11] As a general guideline, failure of a patient to demonstrate improvement in a period of time no longer than 30 days can be interpreted as a red flag.[224]

TABLE 28-18 Interpretation of Findings: Excessive Movement

Hypermobility	Instability
Cause Cumulative stress resulting from neighboring Hypomobility Low level but prolonged overuse Sudden macrotrauma that is not enough to produce instability	Cause Sudden macrotrauma (ligamentous) Hypermobility allowed to progress (ligamentous) Degeneration of interposing hyaline or fibrocartilage (articular)
Findings Subjective complaints of "catching" Good days and bad days Symptoms aggravated with sustained positions Negative lower quarter scan	Findings Subjective complaints of "catching" Good days and bad days Symptoms aggravated with sustained positions Negative lower quarter scan
PPIVM findings Increase in gross PPIVM, with pain at end range	PPIVM findings Increase in gross PPIVM, with pain at end range Presence of nonphysiologic movement (positive stress test) Recurrent subluxations
Intervention Educate patient to avoid excessive range Take stress off joint (mobilize hypomobility) Anti-inflammatories, modalities, if necessary Stabilize, if absolutely necessary	Intervention Falls into three areas: 1. Global stabilization a. Educate patient to avoid activities likely to produce instability b. Total body neuromuscular movement pattern reeducation c. Work or sports conditioning and rehabilitation 2. Local stabilization a. Muscular splinting of region (lifting techniques, twisting on feet, and chin tucking when lifting) b. Bracing with supports (collars, corsets, splints, and braces) c. Regional neuromuscular movement pattern reeducation 3. Segmental stabilization: PNF and active exercises to segment

PNF, proprioceptive neuromuscular facilitation; PPIVM, passive physiologic intervertebral mobility.

TABLE 28-19 Decision Making in Classification Patients into Interventions

Classification Group	Factors Favoring	Factors Against
Manipulation	More recent onset of symptom Hypomobility with spring testing LBP only (no distal symptoms) Low FABQ scores (FABQ < 19)	Symptoms below the knee. No pain with spring testing Increasing episode frequency Peripheralization with motion testing
Stabilization	Younger age Positive prone instability test Aberrant motions present Greater SLR ROM Hypermobility with spring testing Increasing episode frequency Three or more prior episodes	Discrepancy in SLR ROM (>10 degrees) Low FABQ scores (FABQA < 9)
Specific exercise	Strong preference for sitting or walking Centralization with motion testing Peripheralization in direction opposite to centralization	LBP only (no distal symptoms) Status quo with all movements

FABQ, Fear Avoidance Beliefs Questionnaire.

INTERVENTION STRATEg IES

It is essential that the impairments, functional limitations, and disability found during the examination guide the intervention and that the intervention should be dynamic, should direct the responsibility of the rehabilitative process toward the patient, and should have two principal objectives: to relieve the acute pain and to attempt prevention of transition to chronicity.[440] In a Cochrane review on exercise therapy for the treatment of nonspecific LBP, Hayden et al.[441] examined the literature on exercise therapy for patients with acute (11 randomized clinical trials), subacute (6 randomized clinical trials), and chronic (43 randomized clinical trials) LBP, and reported that exercise therapy was effective in decreasing pain in the chronic population, graded activity improved absenteeism in the subacute population, and exercise therapy was as effective as other conservative treatments or no treatment in the acute population.[11] Systematic reviews of various physical therapy interventions for LBP do not provide strong support for any particular treatment approach. One possible reason is the use of heterogeneous samples of patients in many clinical trials. Patients with LBP demonstrate both etiologic and prognostic heterogeneity, which makes it unlikely for any single intervention to have a significant advantage over another in a general population with LBP.[442] T us, it would appear to make more sense to classify patients into more homogenous subgroups that match patients with interventions based on their specific clinical presentation. As a result, several classification approaches have been proposed based on expert opinion and biologic plausibility.[443]

ACUTE PHASE

In the acute phase of rehabilitation for the lumbar spine, the intervention goals are to

- decrease pain, inflammation, and muscle spasm;
- promote healing of tissues;
- increase pain-free range of segmental motion;
- regain soft-tissue extensibility;
- regain neuromuscular control; and
- allow progression to the functional phase.

T e recommendations concerning bed rest for common, acute LBP have changed over the years.[444] In a 1986 study by Deyo et al.,[445] primary care physicians in the walk-in clinic of a public hospital found that the prescription of 2 days rest was equivalent to a prescription of 7 days in terms of pain and function. Moreover, a prescription of 2 days rest was associated with fewer days of sick leave. In 1995, Malmivaara et al.[446] showed that continuation of daily activity to the extent tolerable resulted in a more rapid recovery than either bed rest or back-mobilizing exercises. T e most recent guidelines (2000), based on the results of several randomized studies, advise avoiding bed rest to the extent possible.[447] A study by Rozenberg et al.[440] found that for patients with acute LBP, normal activity is at least equivalent to bed rest. T ese authors recommended that prescriptions for bed rest, and thus for sick leaves, should be limited when the physical demands of the job are similar to those for daily life activities.[440]

Tissue loading during walking has been found to be below levels caused by many specific rehabilitation tasks, suggesting that walking is a wise choice as an initial aerobic exercise for general back rehabilitation.

Pain relief may be accomplished initially by the use of modalities such as cryotherapy, electrical stimulation, and gentle exercises and occasionally by the temporary use of a spinal brace. T ermal modalities, especially ultrasound, with its ability to penetrate deeply, may be used after 48–72 hours. Patient education should be emphasized during this phase. Information about activities to avoid should be given, in addition to advice about adopting positions of comfort. Once the pain and inflammation are under control, the intervention can progress toward the restoration of full strength, ROM, and normal posture.

Macedo et al., in a systematic review of 14 randomized controlled trials examining the effectiveness of motor control exercises for nonspecific LBP, found that motor control, when used in isolation or with additional interventions, is effective in decreasing pain and disability related to nonspecific LBP.[448]

Although there is some evidence to support the remediating effects of lumbar stabilization exercises on some of the muscle impairments identified in patients with LBP,[449–451] the clinical efficacy of this intervention seems to vary, especially when compared to other exercise interventions, or to manual therapy. In light of this variable clinical success, Hicks et al.[427] suggested a clinical prediction rule (CPR) to identify specifically patients with LBP, who are likely to exhibit short-term improvement with lumbar stabilization exercises. Four variables were found to possess the greatest predictive power for treatment success:

1. Age less than 40 years.
2. Average SLR of 91 degrees or greater.
3. T e presence of aberrant lumbar movement.
4. A positive prone instability test (see "Special Tests" section)

When at least three of these variables were present, the positive likelihood ratio for achieving a successful outcome was 4.0, increasing the probability of success from 33% to 67%.[427] A later study by Rabin et al. indicated that a modified version of the above CPR, which contained only two of the original four items (the presence of aberrant lumbar movement, and a positive prone instability test), yielded a better predictive validity.

T e benefits of a well-developed diagnostic CPR for patients with LBP may include reducing the need for unnecessary tests, identifying patients who are likely to benefit from referral to other services and/or further investigations, improving the efficiency of the clinical assessment, reducing the cost of care, enabling more timely initiation of treatment, and informing treatment decision-making.[443] T ree diagnostic LBP CPRs that have undergone validation were identified in a systematic review by Haskins et al.:[443] a tool to assist in the identification of patients with lumbar spinal lateral recess stenosis, and two tools designed to assist in the identification of patients presenting with inflammatory back pain;

- Lumbar spinal lateral recess stenosis. Older age, pain with standing/walking, and relief with sitting/bending were identified as independent predictors.

- Inflammatory back pain. T is term refers to a group of related disorders, including ankylosing spondylitis, psoriatic spondyloarthritis, reactive spondyloarthritis, spondyloarthritis associated with inflammatory bowel disease, and undifferentiated spondyloarthritis. While the CPRs are not intended to diagnose spondyloarthritis, they are designed for early identification of these disorders which is integral to their successful management. T e predictors for this group included age at onset <40 years, insidious onset, morning stiffness >30 minutes, improvement in back pain with exercise but not with rest, awakening because of back pain during the second half of the night only, and alternating buttock pain.[443]

Manual therapy is an intervention frequently used by physical therapists in the management of patients with LBP and is recommended by several clinical practice guidelines and systematic reviews for the management of acute, subacute, and chronic LBP.[442] Such manual therapy techniques may include myofascial release, grade I and II joint mobilizations, massage, gentle stretching, and muscle energy techniques. Manual or mechanical traction may be used for patients with IVD herniations. Conflicting results from randomized trials and systematic reviews on the effectiveness of manipulation suggest that while some patients respond rather dramatically, others may not experience much improvement.[452] T e variety of conclusions in trials of manipulation may be attributable to the failure of researchers to adequately consider the importance of classification. Studies by Flynn et al.[453] and Childs et al.[452] have identified a clinical prediction rule for classifying whether a patient will benefit from spinal manipulation. T e five variables identified include

- current episode of LBP less than 16 days duration;
- no symptoms distal to the knee;
- less than 19 points on the FABQ;
- at least one hypomobile segment in the lumbar spine; and
- at least one hip internal rotation greater than 35 degrees.

T e spinal manipulation used was described as follows. T e patient lies in the supine position with their hands clasped behind the neck, and the clinician stands on the side opposite to the site to be manipulated. T e patient is passively side bent away from the clinician, by sliding the patient's pelvis toward the clinician. While stabilizing the pelvis against the table with one hand, the clinician then passively rotates the patient's trunk toward them using the other hand. A quick posterior and inferior thrust is then applied by the clinician to the ASIS.

In the Flynn et al. study, the presence of four out of five variables in the CPR increased the likelihood of success with spinal manipulation from 45% to 95%.[453] Using the same CPR, the Childs et al.[452] study compared with patients who were negative on the CPR and received exercise, the odds of a successful outcome among patients who were positive on the CPR and received manipulation were 60.8 (95% CI: 5.2–704.7). T e odds were 2.4 (CI: 0.83–6.9) among patients who were negative on the CPR and received manipulation and 1.0 (CI: 0.28–3.6) among patients who were positive on the CPR and received exercise. A patient who was positive on the CPR and received manipulation has a 92% chance of a successful outcome, with an associated number needed to treat for benefit at 4 weeks of 1.9 (CI: 1.4–3.5). In contrast, patients who received only exercise were eight (95% CI: 1.1, 63.5) times more likely to experience a worsening of disability. T e number needed to treat with manipulation to prevent one additional patient from experiencing a worsening in disability was 9.9 (95% CI: 4.9, 65.3).[454]

A pragmatic rule has also been published to predict dramatic improvement based on only two factors:

- Duration is less than 16 days.
- Not having symptoms distal to the knee.

If these two factors were present, patients had a moderate to large shift in probability of a successful outcome following application of thrust manipulation (+ LR = 7.2; 95% CI: 3.2, 16.1).[455]

Cleland et al.[456] used this CPR in a case series of patients with LBP, to assess its accuracy for predicting outcomes using other manipulation techniques. Eleven of the twelve patients (92%) in this case series, who satisfied the CPR and were treated with two different thrust techniques, the previously utilized general lumbopelvic technique, and a side-lying rotational technique, demonstrated a successful outcome in two visits.[456] T e study concluded that patients with LBP, who satisfy the CPR may obtain a successful outcome with either manipulation technique directed at the lumbopelvic region.[456] T e alternative lumbar manipulation technique used in this study was described as follows. T e patient is positioned in side lying, and the clinician stands to face the patient. T e clinician then flexes the patient's top leg until there is movement detected at the selected segmental interspinous space, at which point the patient's foot is placed in the popliteal fossa of the bottom leg. Next, the clinician grasps the patient's bottom shoulder and arm and introduces trunk side bending toward the table and contralateral rotation until motion is again felt at the specified interspinous space. Maintaining the patient's positional setup, the patient is rolled toward the clinician. Using the arm and body, the clinician applies a high-velocity, low-amplitude thrust of the pelvis in an anterior direction. T e two groups receiving thrust manipulation felt significantly better than a group receiving nonthrust mobilization at 1 week, 4 weeks, and 6 months.[457]

A secondary analysis by Fritz et al.[458] examined the relationship between judgments of passive accessory mobility assessments and clinical outcomes after two different interventions, stabilization exercise alone or thrust manipulation followed by stabilization exercise.[11] T e mean duration of symptoms for patients included in the analysis was 27 days (range, 1–594). Patients who were assessed to have a lumbar hypomobility on physical examination demonstrated more significant improvements with the thrust manipulation and exercise intervention than with stabilization alone.[458] T ese findings would seem to suggest that assessment of hypomobility, in the absence of contraindications, is sufficient to consider use of thrust manipulation as a component of comprehensive treatment.[11]

Finally, beyond the use of a CPR, a randomized controlled trial[459] (n = 210) in patients with subacute and chronic LBP that divided patients randomly to receive thrust manipulation, back school intervention, or individualized physical therapy intervention, found the reductions

in disability was significantly higher for the manipulation group at discharge and 12 months.[11]

A few studies have included flexibility training.[460–462] Only one has showed that flexibility training showed an increase in trunk extensor flexibility, [460] although this functional gain was only temporary.

CLINICAL PEARL

Studies have demonstrated increasing evidence that the subacute-stage postinjury (4–12 weeks) is a critical period in preventing disability.[463]

FUNCTIONAL/CHRONIC PHASE

It is worth noting that trunk strength, flexibility, aerobic conditioning, and postural education have all been found to have a significant preventative effect on the occurrence and recurrence of back injuries.[333,448,464,465] T us, physical therapy, with its emphasis on the restoration of functional motion, strength, and flexibility, should be the cornerstone of both the intervention and the preventative processes in LBP.

T e goals of this phase are

- to achieve significant reduction or to complete resolution of the patient's pain;
- restoration of full and pain-free vertebral ROM;
- full integration of the entire upper and lower kinetic chains;
- complete restoration of respiratory function; and
- restoration of thoracic and upper quadrant strength and neuromuscular control.

T e number of physical therapy sessions required to provide relief for nonspecific LBP varies widely. T e factors provided to explain this variance include the medical diagnosis, duration of the complaint, prior therapy, and the patient's age and gender.[466] Evidence on the effectiveness of physical therapy for the management of chronic spine disorders is limited. A systematic review by the Philadelphia Panel[467] suggested there was "good evidence to include stretching, strengthening, and mobility exercises" in treatment programs directed toward the management of chronic LBP. In the past decade, the results of randomized clinical trials on meta-analysis have provided various degrees of support for the efficacy of specific, nonsurgical physical interventions (that may be delivered by physical therapists) for the management of spine disorders. A number of studies have reported that intensive exercise reduces pain and improves function in patients with chronic LBP.[468–470] In addition, exercise programs that combine aerobic conditioning with specific strengthening of the back and legs can reduce the frequency of recurrence of LBP.[471] However, evidence on the efficacy of care specifically provided by physical therapists is more limited.[472–485] Although there is evidence to suggest that some interventions (e.g., exercise, spinal manipulation, massage) that may be delivered by a physical therapist are efficacious in the management of spine conditions, evidence on the efficacy of care specifically provided by physical therapists is less conclusive.[486] T e RCTs that have been conducted are all limited because of small sample sizes, heterogeneous samples, or lack of standardized treatments.[486]

Costa et al.[487] used a placebo-controlled randomized control trial to examine the use of motor control exercises in 154 patients with chronic LBP. Interventions consisted of specific motor control exercises directly to the multifidus and transversus abdominis or nontherapeutic modalities.[11] Short-term outcomes demonstrated small but significant improvements in favor of the motor control group for both patient activity tolerance and global impression of recovery.[11]

T ree major exercise protocols for the management of LBP have emerged over the past 40 years: Williams flexion exercises,[488,489] McKenzie exercises,[282,490] and spinal stabilization exercises.[114,491–493]

WILLIAMS FLEx ION Ex ERCISES

Dr. Paul Williams first published his exercise program in 1937 for patients with chronic LBP, in response to his clinical observation that the majority of patients who experienced LBP had degenerative vertebrae secondary to degenerative disk disease. According to Williams, "Man, in forcing his body to stand erect, severely deforms the spine, redistributing body weight to the back edges of the IVDs in both the low back and neck."[488]

Conceptually, Williams believed that the goal of exercise was to reduce the lumbar lordosis or to flatten the back through strengthening exercises for the abdominal muscles (to lift the pelvis from the front) and strengthening exercises for the gluteal muscles (to pull the back of the pelvis down). Williams designed a group of six exercises to address these issues:

1. *T*runk *fl*exion or sit-up. Although the instructions that Williams gave to perform this exercise were erroneous, a variation of this exercise, the crunch, forms the cornerstone of many modern exercise protocols.
2. Posterior pelvic tilt. With the exception of patients with IVD lesions,[494] the posterior pelvic tilt exercise, outlined later, is still widely recommended. However, due to the fact that they can cause increased compression loads on the lumbar spine,[495] they should be prescribed with caution.
3. *T*runk *fl*exion or bilateral knees to chest. Like the posterior pelvic tilt exercise, this exercise is not recommended for patients with IVD lesions. However, it may provide comfort to patients with spinal lateral recess stenosis.
4. Long sit and reach. T is exercise is no longer recommended because of the stress it places on the soft tissues of the low back. Williams himself acknowledged that this exercise would not be appropriate for patients with sciatica.
5. Iliotibial band stretch in the *f*ront lunge position. Although adaptive shortening of the iliotibial band may be a contributing factor in LBP, as suggested by Williams, better stretches for this structure exist.
6. Stand to squat or stand to sit. T is exercise was recommended because of its ability to strengthen the gluteal muscles. T is exercise has since been incorporated into many spinal stabilization protocols.

Although the use of William's exercises has decreased over the years, the exercises are still indicated for those patients who experience an increase in symptoms when moving into spinal extension, and in those cases where the goal is to widen the intervertebral foramina (lumbar spinal lateral recess stenosis) and gap the zygapophyseal (facet) joints temporarily, thereby reducing nerve root compression.

McKenzie Approach

In many respects, the McKenzie approach (see also Chapter 22) contradicts Williams basic assertions that the lumbar lordosis is harmful. McKenzie initially theorized that the development of LBP is primarily due to three predisposing factors: prolonged sitting in the flexed position, the frequency of flexion, and a lack of extension range.[282] As a result, the early versions of the McKenzie approach focused on regaining spinal extension. T e McKenzie approach has since developed into a system that uses physical signs, symptom behavior, and their relation to end-range lumbar test movements to determine appropriate classification and intervention.

T e physical examination component of the McKenzie method involves a comprehensive assessment of the patient, performed in a series of active and passive movements performed in the beginning, middle, and end ranges of trunk flexion, extension, and combinations of side bending and rotation called side gliding.[282] T e same maneuvers are repeated with the trunk in the neutral position, shifted toward the side of pathology, and away from pathology. T e intent is to gauge the responses, reactions, or effects of spinal loading, and for the presence of the centralization phenomenon. T e patient's response to the examination determines a classification and the direction of preference for therapeutic exercise, with the direction chosen being based on the ability of the position or movement to centralize the patient's symptoms. T e end-range exercises theoretically move the NP away from the side of compression loading, with flexion exercises moving the NP posteriorly and extension exercises moving the NP anteriorly.[282,496–501] T e midrange exercises are better suited for patients with symptoms of neural compression.[502] Postural correction and maintenance of a normal lordosis are also integral parts of the McKenzie program.

Long et al.[503] investigated whether a McKenzie examination and follow-up on 312 patients with acute, subacute, and chronic LBP would elicit a directional preference in these patients. Of the 312 patients, 230 participants (74%) had a directional preference, and these patients were randomized into groups of directional exercises matching the patient's directional preference, directional exercises opposite the patient's directional preference, or nondirectional exercises. Significant reductions in pain, pain medication use, and disability occurred in the directional exercise group that was matched by their directional preference.

T e three major classifications or syndromes are postural, dysfunction, and derangement. Strategically speaking, when utilizing McKenzie protocols, one should rule out a derangement first before treating anything else.

Postural Syndrome

T e key characteristics of the postural syndrome are[490]

- intermittent pain;
- the time factor;
- pain produced by the maintenance of posture/position;
- symptoms provoked by position, but not by movement;
- no deformity (relevant to pain);
- no loss of movement;
- no provocative signs/no pathology;
- aged 30 years and under (usually);
- sedentary workers (underexercised);
- often have cervical and thoracic pain also;
- often have days at a time without pain;
- no pain while active and moving; and
- pain is local to the spine (not referred).

As the postural syndrome is not generally affected by mechanical maneuvers performed by the clinician or the patient, the focus of the intervention is to isolate and subsequently instruct the patient to avoid the offending position(s). T e "slouch/overcorrect" maneuver is taught to the patient. T e patient should sit on the edge of the chair and allow the lumbar spine to slouch into a fully flexed position and allow the head and chin to protrude. He or she must then smoothly move into a fully erect sitting position, achieving a maximal lumbar lordosis, with the head held directly over the spine and with a retracted chin.[490] T is postural motion should be repeatedly performed from the position of "poor" (slouch) posture to the overcorrect position VIDEO.

Dysfunction Syndrome

T e key characteristics of the dysfunction syndrome include[490]

- intermittent pain;
- no time factor;
- pain produced at end position or movement of shortened structures;
- pain relief with relief of stress/unloading shortened tissue;
- always a loss of function/movement;
- no deformity (not rapidly reversible);
- test movements reproduce pain but pain does not worsen as a result;
- over 30 years old except where trauma or derangement is a causative factor; and
- poor posture often underexercised.

T e symptoms related to the dysfunction syndrome tend to be related to movement and become evident in the difficulty or inability of the patient to accomplish end range of movement, most frequently in the extremes of flexion and extension. T e intervention goal for the dysfunction syndrome is the restoration of function or movement of the adaptively shortened tissue using frequent repetition of restricted end-range exercises. T e stretches need to be performed daily every 2–3 hours to achieve the lengthening of adaptively shortened soft tissues. T is usually needs to be continued for a 4–6-week period or until the patient can fully stretch without any end-range pain. T e following instructions must be given to the patient[490]:

- Stretch in the direction of movement loss and end-range pain.

- Allow elongation without microtrauma.
- Pain produced by stretching must stop shortly after the release of stress (persisting pain afterward indicates overstretching).
- Peripheralization of symptoms should never occur.
- Stretching must be strong enough to reproduce discomfort or some pain.
- Must regularly be performed during the day (15 times/2 hr).

Derangement Syndrome

The key characteristics of the various derangement syndromes are

- often constant pain;
- time factors (diurnal cycle);
- pain brought on or increased by certain movements/positions (repetition/sustaining usually worsens pain);
- pain decreased or abolished by other movements/positions (repetition/sustaining usually improves the condition);
- always a loss of movement/function;
- deformity of kyphosis/scoliosis is common (derangements 2 and 4, respectively—see Chapter 22); and
- deformity of accentuated lordosis uncommon (derangement 7—see Chapter 22).

McKenzie classifies derangement of the lumbar spine into seven categories on the basis of the location of symptoms and the presentation of fixed antalgias responsive to end-range loading in directions other than that within which complaints are caused.[282,504] Derangements that are considered to be anterior require strategies containing a flexion component, whereas those that are considered to be posterior involve strategies incorporating an extension component. In most cases, these may be conducted within the sagittal plane, but flexion and extension strategies may, in other cases, be combined with coronal or transverse motions for the best mechanical and symptomatic responses.[490] The theoretical model of the derangement syndrome involves the concept of displacement of the NP/annulus.

The intervention goal for the derangement syndrome is to reduce the derangement by altering the position/shape of the NP/annulus using restricted end-range loading for a prolonged period of time and then to maintain the reduction and aid recovery of function.[490] Mechanical treatment is dependent on the mechanical diagnosis for derangements. The interventions for derangements 1–7 are outlined in Table 28-20. The sequential extension progression advocated by McKenzie, initiated once the patient is able to tolerate prone lying (Fig. 28-17), involves prone on elbows (Fig. 28-52), prone push-up (Fig. 28-53) VIDEO, and extension in standing (Fig. 28-54) VIDEO.

The McKenzie method has been tested for intraobserver variability, with differing results.[293,324,505] In a recent study by Long et al.,[503] the McKenzie approach using exercise prescription based on a directional preference demonstrated significantly better outcomes than comparison groups performing exercise away from a directional preference.

Several outcome studies have examined the effectiveness of the McKenzie method compared with that of other approaches.[506–509] Ponte et al.[506] compared the effectiveness of the McKenzie method with that of the Williams approach and found that the McKenzie method demonstrated greater improvements in pain intensity and lumbar ROM than the Williams protocol. However, this study had a small sample size (22 subjects), and subjects were not randomly assigned but rather assigned by the referring physician to a treatment group.

Nwuga and Nwuga[507] also compared the effectiveness of the McKenzie method with that of the Williams approach. Sixty-two females, aged 20–40 years and all diagnosed with a prolapsed IVD in the lumbar spine, were assigned to either the McKenzie group or the Williams group. Similar conclusions were drawn from this study as from the Ponte study, namely that the McKenzie method demonstrated greater improvements in pain intensity and lumbar ROM than the Williams protocol.[507]

Stankovic and Johnell performed two separate outcome studies (1989 and 1994) that compared long-term patient outcomes following treatment with either the McKenzie approach or with patient education alone in a mini back school.[508,509] A mini back school involves education of the patient in the mechanics of the spine, proper posture, and safe lifting techniques. The 1989 study assessed six variables in 100 employed patients with acute LBP: return to work, sick leave during recurrences, recurrences of pain during the year of observation, pain, movement, and the patient's ability to self-help. The McKenzie method was found to be superior in four of the six variables. The two variables that showed no significant difference were sick leave during recurrences and patient's ability to self-help.[509] The 1994 study was a continuation of the 1989 study and used the same subjects. The later study showed that subjects who received McKenzie treatment had significantly fewer recurrences of pain and recurrent episodes of sick leave compared with the subjects who received mini back school education.[508]

A randomized controlled comparative trial with an 8-month follow-up period was conducted by Petersen et al.,[483] which compared the effect of the McKenzie treatment method with that of intensive dynamic strengthening training in patients with subacute or chronic LBP. Two-hundred and sixty consecutive patients with LBP and at least 8 weeks duration of symptoms (85% of the patients had more than 3 months duration of symptoms) were randomized into two groups: Group A was treated with the McKenzie method (n = 132) and Group B was treated with intensive dynamic strengthening training (n = 128). The treatment period for both groups was 8 weeks at an outpatient clinic, followed by 2 months of self-training at home. Treatment results were recorded at the end of the treatment period at the clinic, then 2 and 8 months after. The study concluded that the McKenzie method and intensive dynamic strengthening training seem to be equally effective in the treatment of patients with subacute or chronic LBP.

The reasons for the positive measure changes observed in the McKenzie treatments remain unclear.[510] Schnebel et al.[502] suggested that the positive results might be related to activation of the gate control mechanisms or relaxation and/or decompression of neural tissues. Porterfield and De Rosa[511] believed that the application of controlled forces to the spine

TABLE 28-20 Intervention of Derangements 1—7

Derangement	Description	Intervention
1	Central or symmetrical pain across L4–5, with rarely buttock or thigh pain and no deformity This indicates a minor posterior disk disturbance	1. Reduction by application of extension principle 2. Maintenance of reduction by a. maintenance of lordosis b. sitting with lumbar support c. frequent performance of extension exercises 3. Recovery of function by a. flexion procedures (lying first), followed by extension procedures: prone lying (Fig. 25-20), prone on elbows (Fig. 28-52), prone push-up (Fig. 28-53), and extension in standing (Fig. 28-54). 4. Prophylaxis: a. Continuation of exercises as directed. Patients can self-treat b. Follow advice (especially regarding the avoidance of, or proper mechanics associated with, prolonged bending and sitting)
2	Central or symmetric pain across L4–5, with or without buttock and or thigh pain, with deformity of lumbar kyphosis Indicates a major posterior-central disk disturbance. A progression of derangement 1 and can easily worsen to a derangement 4 or 6	1. Reduction of deformity until the prone position can be obtained easily 2. Further treatment as for derangement 1
3	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain and no deformity A minor posterolateral disk disturbance A progression of derangement 1	1. Reduction as for derangement 1 2. If no centralization or reduction of pain occurs, the application of unilateral procedures is indicated. 3. Once centralization or reduction of pain is achieved, further treatment as for derangement 1
4	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain and with deformity of lumbar scoliosis Typically a major posterolateral disk disturbance and can be considered a progression of derangement 2 or 3	1. Reduction of derangement: a. Lateral shift correction for lateral component of derangement b. Extension procedures for reduction of posterior component c. Maintenance of lordosis for stabilization of reduction 2. If following reduction of deformity no centralization occurs the application of unilateral technique is necessary 3. Once centralization is achieved, further treatment as for derangement 1
5	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain. There is leg pain extending below the knee The pathogenesis is a posterolateral disk disturbance with impingement on nerve root and dural sleeve Progression of derangement 3 or 4	Treatment of an adherent nerve root: 1. Stretching by flexion procedures 2. Followed by extension procedures to prevent recurrence of derangement
	Intermittent sciatica may be caused by a disk bulge. Flexion in both standing and lying enhance pain; repetition worsens symptoms. It may be caused by an adhesive or tethered nerve root. This is labeled as an adherent nerve root and flexion in standing enhances pain but repetition does not necessarily worsen the symptoms	Treatment of disk bulge: reduction of derangement as treatment of derangements 1 or 3

TABLE 28-20	Intervention of Derangements 1–7 (Continued)	
Derangement	**Description**	**Intervention**
6	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain. There is leg pain extending below the knee and a deformity of sciatic scoliosis The most frequent cause is a major posterolateral disk disturbance with impingement on the nerve root and dural sleeve	If movement or postures/positions does not reduce sciatica: no treatment utilizing movement or positions is possible at this stage If sciatica is reduced by movement or positions then proceed with a reduction of deformity as with derangement 2 or further reduction as for derangements 3 and 1
7	Asymmetrical or asymmetrical pain across L4–5 with or without buttock and/or thigh pain and a deformity of accentuated lordosis Involves an anterior or anterolateral disk disturbance	Reduction of derangement utilizing flexion procedures

The aim of the intervention in derangement syndrome is to reverse derangement 2—6 by shift correction or extension principle to resemble derangement 1 (centralization).

through active exercise or manual techniques might temporarily reduce pain levels by altering the fluid dynamics of injured tissue.

Spinal Stabilization Exercises

The core, which includes the muscles and joints of the abdomen spine, pelvis, and hips, is the kinetic link that facilitates the sequential transfer of torques and angular momentum between the lower and upper extremities.[512] The boundaries of the core include the diaphragm (superior), abdominal and oblique muscles (anterior-lateral), paraspinal and gluteal muscles (posterior), and the pelvic floor and hip girdle (inferior).[513] The inherent nature of these muscular boundaries produces a corset-like stabilization effect on the trunk and spine.[514] Stabilization is the process of decreasing abnormal or excessive symptomatic translations about articulating joint surfaces.[515] Through mechanical modeling, various studies have described the requirements for a stable spine to be a combination of energy wells (potential energy state and the relationship between spinal segments), whole body stability (factors that respond to loads or perturbations), elastic energy and stiffness (joint stiffness as a result of muscular activation), and sufficient stability (adequate activation for functional movement).[213,515] Although a definitive description of lumbar instability has yet to be agreed upon, there is general agreement that it involves a loss of the spine's ability to maintain its pattern of displacement under normal physiological loads.[516] Thus, the basic premise of spinal stabilization (core strengthening, dynamic stabilization, trunk stabilization, and lumbopelvic stabilization) exercises is to teach the patient with LBP how to maintain functional levels by dynamically stabilizing the involved segments (increasing the segmental stiffness) with increased muscular support. This increased muscular support can then be used to help maintain the neutral zone.

There is evidence suggesting that therapeutic exercise is effective in the treatment of nonspecific back pain,[517–520] although there is insufficient evidence to conclude with absolute certainty which theoretical mechanism of lumbar stabilization would be most beneficial in the management of patients with lumbar segmental instability.[88] Until recently, there have been two popular core stabilization rehabilitation strategies[201,515,521]:

FIGURE 28-52 Prone on elbows.

FIGURE 28-53 Prone push-up.

FIGURE 28-54 Extension in standing.

1. The motor control exercises approach, which emphasizes specific training exercises for local muscles.
2. The general exercise approach, which include exercises for global muscles.

A third strategy has been introduced by Behm et al.,[522] which proposes a functional model that maintains the local stabilizers and separates the global muscles into mobilizers and transfer load categories. The transfer load group represents those muscles with axial-appendicular attachments (i.e., gluteus maximus, gluteus medius, hip adductors, rectus femoris, iliopsoas, trapezius, latissimus dorsi, deltoid, and pectoralis major) that transfer force and momentum between extremities and core along the kinetic chain.[522]

Theoretically, local muscles are superior to global muscles in controlling shear loads and are thus strengthened first as the inclusion of global muscle strengthening too early in the program may be deleterious. Before the stabilization progression can begin, the involved structures must be permitted to heal beyond the acute stage of healing. This can be achieved with patient education about the anatomy and function of the core muscles, and with exercises that involve only lower and/or upper extremity motion, while avoiding specific trunk exercises and excessive trunk motion (see "Clinical Instability of the Lumbar Spine" section).

Stretching Exercises

Muscle flexibility should be addressed according to patient tolerance. In individuals suspected to have instability, stretching exercises should be used with caution, particularly ones encouraging end-range lumbar flexion.[420] Poor flexibility may cause excessive stresses to be borne by the lumbar motion segments. For example, adaptively shortened hip flexors and rectus femoris muscles can cause an extension and rotation hypermobility in the lumbar spine. Occasionally, stretching both the anterior and the posterior thigh muscles is beneficial. However, most of the time, only one should be stretched, and the decision is based on the diagnosis:

- The patient with spinal lateral recess stenosis or a painful extension hypomobility, and who responds well to lumbar flexion exercises, should be taught how to stretch the hip flexors and rectus femoris while protecting the lumbar spine from excessive lordosis.
- The patient with a painful flexion hypomobility or IVD herniation, and who responds well to lumbar extension exercises, should be taught how to stretch the hamstrings while protecting the lumbar spine from flexing.

Stretches should be applied and then taught. The goal of stretching is to perform the technique, while maintaining the pelvis in its neutral zone, to avoid excessive anterior or posterior pelvic tilting.

Aerobic Exercise

The importance of aerobic exercise cannot be overemphasized, both in reducing the incidence of LBP[523] and in the intervention for patients who have LBP.[524] Aerobic fitness should be maintained. The following aerobic exercises may be used as tolerated:

- walking and jogging on soft, even ground;
- upper body ergometer;
- indoor cross-country skiing machines; and
- water aerobics.

Proprioceptive Neuromuscular Facilitation

Two of the more commonly used forms of proprioceptive neuromuscular facilitation (PNF) exercises in lumbar spine rehabilitation are rhythmic stabilization training (RST) and combination of isotonic (COI) exercises[525]:

- RST technique. Uses isometric contraction of antagonist pattern resulting in cocontraction of the antagonist if the isometric contraction is not broken by the clinician. It is used mainly to manage conditions in which weakness is a primary factor and in which stabilization provides stimulation of the agonistic pattern.[526]
- COI technique. Used to evaluate and develop the ability to perform controlled purposeful movements. It involves the performance of alternating concentric, eccentric, and isometric contractions and is used to treat deficiencies in strength and ROM.[527]

Although previous studies have shown that isometric training can have positive effects on back pain,[525,528] information on the effectiveness of dynamic and combined dynamic–static contraction exercises for trunk muscle stabilization and strength is scarce. Kofotolis and Kellis[525] examined the effects of RST and COI on trunk muscle endurance, flexibility, and functional performance in subjects with chronic LBP. Eighty-six women (40.2 ± 11.9 [mean ± SD] years of age) who had complaints of chronic LBP were randomly assigned to three groups: RST, COI exercises, and control. Subjects were trained with each program for 4 weeks, with the aim of improving

trunk stability and strength. The exercises were performed with the patient in sitting over the edge of the treatment table and consisted of the subject flexing and then extending the trunk against the clinician's variable manual resistance and maintaining static positions for 5 seconds. Multivariate analysis of variance indicated that both training groups demonstrated significant improvements in lumbar mobility (8.6–24.1%), static and dynamic muscle endurance (23.6–81%), and Oswestry Index (29.3–31.8%) measurements, suggesting that static and dynamic PNF programs may be appropriate for improving short-term trunk muscle endurance and trunk mobility in patients with chronic LBP.

Back School

Several back schools and back rehabilitation programs have been developed to teach people proper lifting technique and body mechanics. These programs are aimed at groups of patients. They include the provision of general information on the spine, recommended postures and activities, preventative measures, and exercises for the back.

The efficacy of back schools, however, remains controversial.[529,530] Cohen et al.[531] concluded that there is insufficient evidence to recommend group education for people with LBP.

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH LOCALIZED INFLAMMATION

Ligament Tears

As with ligament tears elsewhere in the body, ligament tears of the lumbar spine are normally traumatically induced. Knowledge of the various restraints to the various motions of the lumbar spine can aid in determining which ligament has the potential to be sprained with a given mechanism.

Iliolumbar Ligament Sprain

The iliolumbar ligament, an extremely important structure that stabilizes the lumbar spine on the sacrum and functions to anchor the L5 vertebra onto the S1 vertebral body,[71] is commonly injured.

The iliolumbar ligament sprain, also known as the iliac crest syndrome, has a classic presentation of lower lumbar pain just at or above the medial iliac crest area, with radiation sometimes down the leg. On examination, the SLR and Patrick (FABER) sign are both usually negative; there is no weakness or sensory impairment, and no radicular signs. The diagnosis is confirmed by deep palpation of the iliolumbar ligament in an attempt to reproduce the patient's discomfort. Njoo et al.[532] have provided evidence of good interobserver validity in the diagnosis of this problem in a prospective manner. A single injection of lidocaine and steroid provides effective and sustained treatment to this readily accessible area.[533]

Muscle Contusions, Strains, and Tears

Muscle injuries are associated with a history of trauma and are capable of producing a significant degree of discomfort. Two sites are commonly involved in the lumbar region, and strains and tears can occur with relatively little trauma there[534]:

1. The point where the erector spinae group of muscles joins to their common tendon just above and medial to the PSIS.
2. At the gluteal origin on the ala of the ilium, just lateral to the PSIS.

However, muscle pain can also be produced from excessive muscle activity or muscle guarding, which follows an injury to the spine. The intervention for muscle tears involves a gradual and controlled resumption of movements and activities.

Diastasis Recti Abdominis

The female anatomy undergoes tremendous changes during the childbearing year. The musculoskeletal changes that may occur during this time include increased ligament laxity, pelvic floor dysfunction, and diastasis recti abdominis (DRA) (see Chapter 30).[107]

It is important for physical therapists to learn the screening skills and know that a DRA has a potential impact on the stability of the pelvis on a long-term basis.

PRACTICE PATTERN 4F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM OR REFLEX INTEGRITY SECONDARY TO SPINAL DISORDERS

Piriformis Syndrome

The sciatic nerve usually travels below the piriformis. In approximately 15% of the population, however, either the tibial part of the sciatic nerve passes through the belly of the piriformis muscle or the piriformis has two muscle bellies and the nerve passes between the two bellies. Consequently, contraction or tightness of the muscle can often produce radicular symptoms (see Chapter 5).

Piriformis syndrome usually is a diagnosis of exclusion once the more common causes of sciatica have been ruled out.[535] Robinson[536] listed six cardinal features of piriformis syndrome: (1) a history of trauma to the sacroiliac and gluteal regions; (2) pain in the region of the sacroiliac joint, greater sciatic notch, and piriformis muscle, extending down the lower limb and causing difficulty in walking; (3) acute exacerbation of the symptoms by lifting or stooping; (4) a palpable, sausage-shaped mass over the piriformis muscle, during an exacerbation of symptoms, which is markedly tender to pressure (this feature is pathognomonic of the syndrome); (5) a positive result on the SLR test; and (6) gluteal atrophy, depending on the duration of symptoms.[535]

The intervention for piriformis syndrome depends on the suspected pathology. If muscular spasm and tightness are the suspected etiology, then an aggressive stretching and massage

of the piriformis program should be instituted.[537] If this conservative approach fails, a local anesthetic block to the muscle should be considered. Surgical neurolysis is considered for recalcitrant cases.

Entrapment Neuropathies of the Medial Superior Cluneal Nerve

The cutaneous innervation of the lower lumbar and gluteal regions has been attributed to the posterior (dorsal) rami of L1–3. Maigne and Maigne[538] observed that the cutaneous innervation of the gluteal region is derived from higher levels of the thoracolumbar region, that is, from T11 to L1. Anastomoses between these nerves are also common. Superior cluneal nerve injury is a well-known cause of chronic pain complicating bone graft harvesting from the posterior iliac crest for spinal fusion.[539,540] The medial superior cluneal (MSC) nerve is the most medial nerve of these nerves. The MSC usually crosses the posterior iliac crest at a distance of approximately 7 cm from the midline.[541] At that point, it becomes superficial by passing through an osseofibrous tunnel, formed by the TLF cranially and the rim of the posterior iliac crest caudally.[541] This tunnel is occasionally a site of compression for the MSC nerve.[538]

According to Maigne,[541] MSC nerve entrapment can be diagnosed and treated using the following criteria:

- a trigger point over the posterior iliac crest, located 7 cm from the midline (corresponding to the nerve compression zone);
- relief of symptoms by nerve block.

INTEGRATION OF PRACTICE PATTERNS 4H AND 4I: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, ROM ASSOCIATED WITH FRACTURES, JOINT ARTHROPLASTY, AND SOFT-TISSUE SURGICAL PROCEDURES

Spondylolysis

Spondylolysis is a bony defect of the pars interarticularis of the spine. The actual defect in the pars covers a broad range of etiologies, from a stress fracture to a traumatic bony fracture with separation.[542] Patients with bilateral pars defects can progress to spondylolisthesis (see the next section).

The exact cause of spondylolysis is unknown, but it is likely related to congenital, acquired (repeated microtrauma), or developmental causes. The acquired type has been attributed to lumbar hyperextension combined with rotation and loading and often occurs in dancers, gymnasts, figure skaters, weight lifters, and football players.[543] Prevalence of spondylolysis ranges from approximately 6–11.5% in the general population.[544] Spondylolysis commonly is asymptomatic, making diagnosis extremely difficult. Those patients with symptoms often have pain with extension and/or rotation of the lumbar spine. Patients with suspected spondylolysis should be evaluated initially with plain radiography, consisting of anteroposterior, lateral, and oblique views of the lumbar spine. The lateral views are most sensitive for detection of pars fractures, and the oblique views are the most specific.[542,545] If plain radiographs are negative or inconclusive, further imaging may be warranted. Currently, controversy surrounds the questions as to whether MRI, CT and single-photon emission CT bone scintigraphy are best to further evaluate these patients.[546–548]

Although no consensus can be reached on the role of nonoperative versus surgical care because of limited investigation and heterogeneity of studies reported, the initial management of a patient with spondylolysis is typically conservative. In a meta-analysis performed by McNeely et al.,[549] the efficacy of physical therapist intervention in the treatment of spondylolysis and spondylolisthesis was systematically reviewed. Of the 71 potential studies, only two of the studies met the relevance criteria of the critical appraisal.[542]Spratt et al.[550] examined the efficacy of trunk extension and flexion treatment programs on 56 patients with radiographic instability (retrodisplacement or spondylolisthesis).[542] Subjects were randomly assigned to one of three groups: a flexion, an extension, or a control group. The flexion and extension groups performed exercises biased into flexion or extension, respectively.[542] At the 1-month follow-up, no treatments were shown to alter ROM or trunk strength. However, patients in the extension group reported less pain, as compared with patients in the flexion and control groups.[542,550] In a study by O'Sullivan et al.,[551] 45 subjects with spondylolysis or spondylolisthesis were divided into two groups: a group that underwent 10 weeks of rehabilitation, with a focus on training of the deep abdominal muscles, and a control group that underwent treatment as directed by their treating practitioner.[542] The group that underwent specific abdominal exercise training had a reduction in pain and disability levels, which was maintained at a 30-month follow-up.[542] The control group showed no significant change throughout the study.[551]

Based on these studies, the physical therapy intervention should strive to correct any muscle imbalances (adaptively shortened hip flexors), increase trunk muscle strength, and educate the patient to avoid activities involving excessive impact and activities involving lumbar hyperextension. Bracing may also be advocated.

Surgical intervention is only indicated after patients have failed conservative management.

Spondylolisthesis

The term spondylolisthesis refers to an anterior slippage and inability to resist shear forces of a vertebral segment in relation to the vertebral segment immediately below it, which usually occurs in the lumbar spine due to a defect in the pars. The most common site for spondylolysis and spondylolisthesis is L5–S1. Frequently, spondylolisthesis leads to spinal instability—the inability of the spine to maintain its normal pattern of displacement when placed under physiological load.[27] Under normal conditions, the anterior slippage of the vertebra is resisted by the bony block of the posterior facets, by an intact neural arch and pedicle, and, in the case of the L5 vertebra, by the iliolumbar ligament. Age appears to be an important factor in the natural history of spondylolisthesis. Children younger than

5 years of age rarely present with spondylolysis, and severe spondylolisthesis is equally rare. The period of most rapid slipping is between the ages of 10 and 15 years, with no more slipping occurring after the age of 20.[295] In the adolescent spine, the zygapophyseal joints are more horizontal than in the adult's allowing more side flexion and rotation, and causing the lumbar disk and posterior column structures to sustain a greater responsibility for mobility control.[552] Higher-grade spondylolisthesis is twice as common in girls as in boys and is approximately four times more common in women than men.[553]

The etiology of spondylolisthesis has been discussed extensively in the literature.[74,295,545,551,554–564] Newman[561] described five groups represented by this deformity, based on etiology:

1. Congenital spondylolisthesis. This type results from dysplasia of the fifth lumbar and sacral arches and zygapophyseal joints.
2. Isthmic spondylolisthesis. This type is caused by a defect in the pars interarticularis, which can include a fracture or elongation of the pars.
3. Degenerative spondylolisthesis. This type usually affects older people and occurs most commonly at the L4–5 level. This type is perhaps the most commonly encountered by the orthopaedic physical therapist.
4. Traumatic spondylolisthesis. This type occurs with a fracture or acute dislocation of the zygapophyseal joint and is fairly rare.
5. Pathologic spondylolisthesis. This type can result from a pathologic process causing a weakening of the pars, pedicle, or zygapophyseal joint.

Spondylolisthesis acquisita, a sixth etiologic category, was added to represent the slip caused by the surgical disruption of ligaments, bone, and disk.

There are two prevailing theories as to the etiology of degenerative spondylolisthesis:

1. Dysfunction of the IVD.[563] The IVD at the level of the spondylolisthesis is subjected to considerable anteriorly directed shear forces and is the main structure that opposes these shear forces, functioning to prevent further slippage and keeping the spinal motion segment in a stable equilibrium. It is postulated that slip progression after skeletal maturity is almost always related to IVD degeneration at the slip level. As the biochemical integrity of the IVD is lost, the lumbosacral slip becomes unstable and progresses. Disk degeneration at the slip level and adult slip progression are likely to develop during the fourth and fifth decades of life. This is unstable mechanical situation leads to symptoms of low back and sciatic pain and may necessitate spinal instrumentation and fusion.
2. Horizontalization of the lamina and the facets or sacrum morphology.[565] A more trapezoidal shape of the vertebral body, or a dome-shaped contour of the top of the sacrum, or both, are found in individuals with slipping. There is also a greater anterior flexion of the lumbar spine than in "normal" individuals of comparable age.[559] A sagittal orientation of the facet joints also could predispose the vertebra to slip.[556]

Other factors such as the lumbosacral angle, ligamentous laxity, previous pregnancy, and hormonal factors impose an increased stress on the L4–5 facet joints, and, as most of the stress is placed anteriorly on the inferior facet of L4, the wear pattern is concentrated at this point, creating a more sagittally orientated joint by way of remodeling.[558]

Whatever the cause, if the syndesmosis maintains the bonds between the two halves of the neural arch, there is no mechanical instability and the patient is asymptomatic, whereas if the syndesmosis is loose, separation occurs during flexion. Repetitive motions that cause fatigue may advance to an acute, spontaneous pars interarticularis weakening, stress fracture, or fracture and a predilection for spondylolisthesis.[552]

Spondylolisthesis is graded according to the percentage of slip. Slip percentage is the distance from a line extended along the posterior cortex of the S1 body to the posteroinferior corner of the L5 vertebra,[566] divided by the anteroposterior diameter of the sacrum. Grading is then performed using the Meyerding classification[567] as follows: grade I, 1–25%; grade II, 26–50%; grade III, 51–75%; grade IV, 76–100%; and grade V (spondyloptosis) more than 100%.

The possible pathologic changes at the adjacent instability segment include instability of the motion segment, IVD space narrowing, and lateral recess stenosis caused by facet degeneration and ligament flavum hypertrophy.[568] Degeneration of the IVD above or below a surgical fusion, and damage to the posterior ligament complex, may also contribute to the development of the lesions, by reducing resistance to shearing forces at the intervertebral level next to the fusion.[568]

Clinically, these patients complain of chronic or insidious midline pain at the lumbosacral junction that is mechanical in nature (is worsened with activity and alleviated with rest), and is exacerbated with lumbar extension and rotation activities.[569] The symptoms usually begin in the second decade and are initially painful but not disabling.[569]However, there is often no correlation with the degree of slip and the level of symptoms. This is because the anterior slippage of the vertebral body usually results in intervertebral foramen enlargement initially. It is only when the neural arch rotates on the pivot formed by its articulation with the sacrum, or there are anterior osteophytes, that encroachment occurs, resulting in nerve root irritation. The spectrum of neurologic involvement runs from rare to more common in the higher grade slips, with the majority of neurologic deficits being an L5 radiculopathy with an L5–S1 spondylolisthesis, but cauda equina impairments can occur in grade III or IV slips. The patient may complain of leg pain, which can have a radicular-type pattern or, more commonly, will manifest as neurogenic claudication. If neurogenic claudication is present, the patient may complain of bilateral thigh and leg tiredness, aches, and fatigue.[557] Questions regarding bicycle use versus walking can help the clinician to differentiate neurogenic from vascular claudication (see Chapter 5). Both cycling and walking increase symptoms in vascular claudication due to the increased demand for blood supply. However, the symptoms of neurogenic claudication worsen with walking but are unaffected by cycling, due to the differing positions of the lumbar spine adopted in each of these activities. Patients with neurogenic claudication are far more comfortable leaning forward or sitting, which flexes the spine more than walking.[562] The position of forward flexion increases the anteroposterior diameter of the intervertebral canal, which allows a greater

volume of the neural elements and improves the microcirculation.

The range of motion of flexion of the lumbar spine frequently is normal with both types of claudication. Some patients are able to touch their toes without difficulty. Strength is usually intact in the lower extremities. Sensation also is usually intact. A check of distal pulses is important to rule out any coexisting vascular insufficiency. Findings such as hairless lower extremities, coldness of the feet, or absent pulses are signs of peripheral vascular disease (PVD). Sensory defects in a stocking-glove distribution are more suggestive of diabetic neuropathy. The muscle stretch reflexes generally will be normal or diminished. If hyperreflexic symptoms and other UMN signs, such as clonus or a positive Babinski test, are found, further investigation is necessary including examination of the cervical, thoracic, and lumbar spine to rule out a lesion of the spinal cord or cauda equina.

A common clinical manifestation is increased lumbar and hamstring muscular tone, which may be associated with a compensatory response secondary to ineffective stabilization of the painful spinal segment.[569]

Differential diagnosis includes coexisting osteoarthritis of the hip, myelopathy, spinal tumors, and infections.

Differential diagnosis of clinical instability associated with spondylolisthesis often requires several clinical and diagnostic tests.[569] Radiographic findings for these patients can be misleading. Multiple scans including different radiographic views are necessary to avoid imaging error, and failure to investigate lateral and oblique views may lead to misdiagnosis in 20% of cases.[570] In a lateral view, taken while the patient is supine, the forward displacement often appears trivial, because it is only when the patient is standing that the true degree of slip is appreciated. Consequently, if spondylolisthesis is suspected, a lateral spot view of the lumbosacral junction must be taken while the patient stands upright, and during flexion and extension of the trunk.[560] However, a patient with LBP who demonstrates a spondylolisthesis on radiograph may have an asymptomatic spondylolisthesis, and, therefore, the source of the back pain requires further investigation. Some authors have suggested that manual palpation is effective in detecting spine instability, simply by determining if the motion is greater than that found with hypermobility.[571,572] However, little evidence exists to support the reliability of palpation mechanisms for spinal instability assessment.[569,573,574]

The intervention for spondylolisthesis depends on the presenting symptoms, rather than the degree of slip, and ranges from conservative to surgical. Current studies investigating both nonoperative and surgical outcomes for individuals with spondylolisthesis are generally poorly defined and suffer from bias, lack of control groups, and blinding of assessors.[575] However, it would appear that conservative intervention is more likely to be successful in the case of a limited slip and sparse clinical findings. Such an approach includes pelvic positioning initially to provide symptomatic relief, followed by an active lumbar stabilization program (Table 28-21), and stretching of the rectus femoris and iliopsoas muscles to decrease the degree of anterior pelvic tilting. O'Sullivan et al.[551] completed a randomized control trial involving subjects with radiologically confirmed spondylolysis or spondylolisthesis, in which a specific exercise group received weekly interventions focusing on training to promote isolation and cocontraction of the deep abdominal muscles and lumbar multifidus.[11] A control group received usual care typically consisting of aerobic exercise, rectus abdominis training, and modalities. At the conclusion of the 10 week program, the specific exercise group demonstrated statistically significant improvement in both pain intensity and functional disability, and these gains were maintained at a 30-month follow-up.

In those cases where conservative measures do not provide adequate relief, or the neurological signs and symptoms appear to be progressing, surgery may be required. During the past decade, numerous patients with lumbar degenerative spondylolisthesis have been treated with decompression and fusion with or without instrumentation.[568] A high fusion

TABLE 28-21 A Three-Phase Rehabilitation Program for a Grade 1 Spondylolisthesis

Phase 1	Phase 2	Phase 3
Abdominal isometrics (in neutral, diagonal, and straight planes)	Continued progression of exercises from Phase 1	Continued progression of exercises from Phases 1 and 2
Cocontraction of multifidi and abdominals in flexion	Contralateral arm and leg raises in prone Prone trunk lifts on the Physioball	Increase in distal weighting and lever length using resistance
Isometric abdominal exercises in hook lying	Rhythmic marching during supine stabilization on Physioball	Multifidi exercises in prone
Multifidi contraction in a flexed position		Sitting and standing exercises with outside resistance to target cocontraction during functional activities
Resisted isometrics using cane (to isolate transverse abdominis) in supine	Abdominal crunches on the physioball Abdominal stabilization during oblique lever changes	Nonlocal muscle strengthening
Cocontraction of the spine during ADLs	Cocontraction of the spine during ADLs	

Data from Cook C, Cook A, Fleming R. Rehabilitation for clinical lumbar instability in a female adolescent competitive diver with spondylolisthesis. J Man Manip Ther. 2004;12:91–99.

rate and satisfactory clinical outcome have been reported. However, a few patients present with recurrent back pain and sciatica after surgery. The possible causes of postoperative pain include inadequate decompression, fibrosis, recurrent IVD herniation, adjacent lateral recess stenosis.[568] Ironically, another cause of postoperative pain is instability of those segments above and below the fusion site.[85]

Lumbago

The term lumbago is used to describe local back pain of a diskogenic origin but also can be used to describe a sudden onset of persistent LBP, marked by a restriction of lumbar movements and reports of "locking." The mechanism of mechanical locking is still a contentious issue.[56,132,576] The severity of each episode varies, from incapacitating to minor discomfort. Although it can occur at any age, lumbago typically affects patients between the ages of 20 and 45 years. The mechanism of injury usually involves a sudden unguarded movement of the lumbar spine, involving either flexion or extension combined with rotation or side bending.

Hypomobilities can be classified as symmetric or asymmetric. If both sides of the joint are involved, the lesion is symmetric, whereas if only one side is involved, the lesion is asymmetric.

INTEGRATION OF PREFERRED PATTERNS 4B AND 4F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, ROM SECONDARY TO IMPAIRED POSTURE, SYSTEMIC DYSFUNCTION (REFERRED PAIN SYNDROMES), SPINAL DISORDERS, AND MYOFASCIAL PAIN DYSFUNCTION

Postural Syndromes of the Lumbar Region

Symmetric impairments of the lumbar spine occur as a result of either acute pain or myofascial and articular tissue shortening from a fixed postural impairment.[84,137,577,578]

A symmetric impairment will not be apparent in the flexion and extension position tests, because, as both are equally impaired, there is no deviation from the path of flexion or extension, but rather the path is shortened or lengthened, depending on which type of impairment (hypomobility or hypermobility) is present. In addition, there is no apparent loss of side bending or rotation, and both sides appear equally hypomobile or hypermobile, with no change in the axis of rotation, except in the case where it ceases to exist, as in bony ankylosis.

Lower Crossed Syndrome

In this syndrome, the erector spinae and the iliopsoas are tight, and the abdominal and gluteus maximus are weak (see Chapter 6). This syndrome results in an anterior pelvic tilt, an increased lumbar lordosis, and a slight flexion of the hip. A number of muscles are adaptively shortened in this syndrome, including the gastrocnemius, soleus, hip adductors, and hip flexors. The hamstrings also are frequently shortened in this syndrome, and this may be a compensatory strategy to lessen the anterior tilt of the pelvis[579] or a result of the weak glutei. Common injuries associated with this syndrome include hamstring strains, anterior knee pain, and LBP.

INTEGRATION OF PRACTICE PATTERNS 4D AND 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, ROM ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION, AND LOCALIZED INFLAMMATION

Lumbar Disk Pathology

Back pain, with or without radiculopathy, is a significant clinical problem. A large percentage of the mechanical causes of back pain, particularly LBP, are attributed to pathologies of the IVD. IVD herniation in the lumbar spine may occur from adolescence into old age. Degenerative changes are the body's attempts at self-healing as the body ages. If part of this healing involves the stabilization of an unstable joint, the joint motion can be reduced by muscle spasms or by increasing the surface area of the joint.[580] The biology of IVD degeneration is not well understood but is thought to be a normal process, as opposed to the pathologic process that occurs with degradation (see Table 28-22 and later discussion).

The diagnoses associated with degenerative disk disease include

- idiopathic LBP;
- lumbar radiculopathy;
- myelopathy;
- lumbar lateral recess stenosis;
- spondylosis;

TABLE 28-22 Comparison of Degeneration and Degradation of the Disk

Degeneration	Degradation
Changes occur to biochemistry in early adulthood and middle age	Vasculogenic degradation of nucleus
Circumferential clefting and tearing of annulus	Circumferential and radial tearing of annulus
No migration of nucleus	Nucleus migrates through radial fissures
Undisplaced	Nucleus herniates through annulus
Disk maintains or increases height	Disk is reabsorbed

- osteoarthritis;
- degenerative disk disease; and
- zygapophyseal joint degeneration.

Disk degeneration appears to involve a structural disruption of the AF and cell-mediated changes throughout the IVD and subchondral bone.[581] Kirkaldy-Willis proposed a system to describe the spectrum of degeneration involving three stages or levels.[73] T e three stages, which have essentially withstood the test of time, are defined as early dysfunction, intermediate instability, and final stabilization.

1. Early dysfunction. T is stage is characterized by minor pathologic changes resulting in abnormal function of the posterior elements, and IVD.[582] Autopsy results show that disk degeneration begins as early as 20–25 years of age.[287] Disk herniation most commonly occurs at the end of this stage, as splits and clefts develop in the annulus, but may also occur during the last stage. Degeneration seems to start early in the upper lumbar spine, with end-plate fractures and Schmorl's nodes related to the vertical and torsional loading of those segments.[44] A Schmorl's nodule represents a dislocation of cartilage tissue through the end plate into the vertebral body. One study[583] provided evidence that a family history of operated lumbar disk herniation has a significant implication in lumbar degenerative disk disease, indicating that there may be a genetic factor in the development of lumbar disk herniation as an expression of disk degeneration.
2. Intermediate instability. T is stage is characterized by laxity of the posterior joint capsule and AF. Disruption of the AF is associated with back pain.[584] All skeletal tissues adapt to increased mechanical demands, but they may not always adapt quickly enough. People who suddenly change to a physically demanding occupation may subject their tissues to an increase in repetitive loading, causing fatigue damage to accumulate rapidly. T e ability of spinal tissues to strengthen in response to increased muscle forces may be restricted by health and age so that fatigue damage accumulates most rapidly in sedentary middle-aged people who suddenly become active.[585]
3. Final stabilization. T is stage is characterized by fibrosis of the posterior joints and capsule, a loss of disk material, the formation of radial tears of the AF, and osteophyte formation.[586] Osteophyte formation around the three-joint complex increases the load-bearing surface and decreases the amount of motion, producing a stiffer and thus less painful motion segment.[581]

Clinical experience has shown that it is possible for the three-joint complex to go through all of these phases with few symptoms generated.

Disk Degradation

Disk degradation is a more aggressive process than the degenerative changes that occur with aging, and although the macroscopic changes are similar to those of age-related degeneration, degradation is a more accelerated process.

Under normal conditions, the NP is contained by the AF. Any disturbance of the balance of these tissue structures may lead to tissue destruction, functional impairment, and LBP.[28] Four main types of lumbar disk herniation are recognized:

1. Protrusion. With a protrusion, or contained herniation, the nuclear material bulges outward through the tear to strain, but not escape from, the outer AF or the PLL. Contained herniations are confined to the central canal. T e disk bulges against the dura and the PLL, producing a dull, poorly localized somatic-type pain in the back and sacroiliac region. Regarding the modes of lumbar disk herniation, Yasuma et al.[587] described the degenerative process of the matrix and concluded that most herniations are protrusions of the NP that occur before the age of 60 years, whereas after that age, prolapse of the AF predominates. Eckert and Decker[588] and Taylor and Akeson,[589] however, found cartilaginous end-plate fractures in 60% of herniated masses, and in approximately 50% of sequestrated fragments, respectively. Because the NP is usually still contained, the patient is likely to feel more pain in the morning after the NP has imbibed more fluid, because of the added volume and the subsequent increase in pressure on pain-sensitive structures. Recent attention has been given to the internal disruption of the NP in a contained herniation.[590] In this condition, the NP becomes inflamed and invaginates itself between the annular layers. Compression of the disk during sitting and bending increases the pain, because the nociceptive structures within the AF are further irritated. T ere is usually no, or minimal, leg pain and no, or minimal, limitation in the SLR test (see Chapter 11).[590]
2. Prolapse. With a prolapse, the nuclear material remains attached to the disk but escapes the AF to bulge posterolaterally into the intervertebral canal. Once a tear to the periphery is opened for the NP, it would seem logical that further stresses can force it to migrate through the tear. However, under normal conditions, the nuclear material is intrinsically cohesive and does not herniate through the AF, even if the AF fibers are weakened by a radial incision.[591]
3. Extrusion. An extrusion describes the finding of nuclear material beyond the confines of the PLL or above and below the disk space, but is still in contact with the disk, as detected on MRI.[29,592]
4. Sequestration. T e migrating nuclear material escapes contact with the disk entirely and becomes a free fragment in the intervertebral canal.

As part of its unnatural history, the disk may or may not travel through each stage of herniation sequentially, producing symptoms that range from a backache to bilateral radiculopathy.

Nerve Compression

Extrusions and sequestrations impinge on nerve tissue. Central extrusions, although relatively rare, may produce UMN impairments if they are sufficiently large to compress the cervical or thoracic spinal cord, and bowel or bladder impairments if they occur in the lumbar spine (cauda equina syndrome).[593] A substantial compression of the root affects the nerve fibers, producing paresthesia and interference with conduction. In 1934, Mixter and Barr suggested that tissue of the IVD extrudes into the spinal canal, compressing and therefore irritating the nerve root and causing sciatic pain.[594] Although

this concept was widely accepted for many years; it has now been demonstrated that mechanical compression of the nerve root alone does not explain sciatic pain and radiculopathy.[595–597] The operative finding that mechanically compressed nerve roots become tender, and results of recent histologic and biochemical studies on herniated lumbar disk tissue, led to the notion of inflammatory induced sciatic pain.[595–598] More recent models of lumbar radiculopathy suggest that the underlying mechanisms probably result, in part, from a local chemical irritant such as proteoglycans released from a disk and creating an inflammatory reaction, an autoimmune reaction from exposure to disk tissues, an increased concentration of lactic acid or a lower pH around the nerve roots.[596,599] Investigators have repeatedly demonstrated inflammatory cells, proinflammatory enzyme phospholipase A2, immunoglobulins, and various inflammatory mediators in herniated disk tissues.[595,600] It is also thought that neovascularization in herniated disk tissue could promote the formation of granulation tissue,[597,598,601] and in association with blood vessels, deposits of immunoglobulins have been reported.[596]

The presence of inflammation in disk herniations could explain the clinical findings of improvement in radicular pain following the administration of corticosteroid or nonsteroidal anti-inflammatory drugs (NSAIDs).

The diagnosis of a disk herniation is based largely on the history and physical examination findings and, on occasion, imaging test results. The patient's complaints of pain usually are related to the following factors:

- Whether excessive imbibition or excessive dehydration has occurred to the disk.[345] Excessive imbibition, which results from a prolonged absence from compressive forces, may place a mechanical stress on the innervated outer AF, or other posterior structures, resulting in pain and decreased mobility following recumbency. Dehydration of the disk results from the application of prolonged compressive forces, which reduces the size of the disk and allows for excessive translational segmental mobility and compression on normally unloaded segmental structures.[345] This is mechanism results in increased symptoms and decreased mobility as the day progresses.
- The direction and extent of the protrusion can impact the patient's symptoms. Posterior or posterolateral protrusions are the most common and because these types may involve pressure against the PLL or against the dura mater, the patient may describe a severe midline backache or pain that spreads across the back into the buttock and thigh regions. An anterior protrusion may cause pressure against the ALL resulting in back pain but no neurological signs. Larger posterior protrusions may cause compression of the spinal cord with resulting loss of bladder control and saddle anesthesia.
- Whether the nerve root is involved. An ischemic nerve root responds with an increase in symptoms if a movement increases compression to the nerve root.[345] Such movements include lumbar extension and ipsilateral side bending. This is probably why patients with nerve root involvement adopt a posture of flexion and contralateral side bending, although occasionally this posture can result in an increase in symptoms because of an increase in tension and a decrease in intraneural circulation.[345] In these cases the patient is likely to adopt a posture of flexion and ipsilateral side bending.

The ability of the disk to maintain its hydrostatic pressure is a factor of previous extrusions or sequestrations, disk surgery, and the degree of disk degeneration.[160,581] Theoretically, if the hydrostatic pressure is maintained following a posterolateral disk protrusion, the patient will have increased pain with flexion, flexion with contralateral rotation, or side bending.[345] These symptoms tend to be increased with repetition of those motions but improved with motions in the opposite directions, although initially those symptoms may increase, depending on the position of the NP.[345]

The following are the most common findings, although these findings will differ slightly based on the level of the disk protrusion/prolapse (see later).

- The patient reports a gradual increase of pain with inactivity, or if participating in any activity that increases the intradiskal pressure (e.g., sitting, coughing, straining, bending forward). When the patient arises first thing in the morning, there may be an increase in pain. Sometimes, standing, walking, or lying prone may be reported to lessen the pain.
- The location and distribution of the symptoms will vary according to the structures involved e.g. ligament, nerve root, spinal cord, or cauda equina (see later).
- AROM testing typically reveals a limitation in forward bending and backward bending. The decrease in backward bending may be improved, or the symptoms become more centralized if any lateral shift of the spinal column is corrected first. Depending on the side of the lesion, side bending or rotation to one side may be more preferable than the opposite side.
- Repeated motion testing may highlight a peripheralization of symptoms with forward bending, and a centralization of symptoms with backward bending.
- Positive SLR test.
- Positive, hyporeflexive, muscle stretch reflex is dependent on the level of the lesion.
- Neurological symptoms in dermatome and possibly myotome distribution of affected nerve roots.

Imaging results can be misleading. Anatomic evidence of a herniated disk is found in 20–30% of imaging tests (myelography, CT, and MRI) among normal persons.[224,432,433] Conventional physical examination for a suspected disk herniation consists of tests for key muscle strength and lumbar ROM, and muscle stretch reflex and sensory testing, and dural mobility tests such as the SLR test. It must be remembered that no single test in the physical examination has a high diagnostic accuracy alone for disk herniation.[276]

Several plausible diagnoses, depending on the distribution of symptoms, must be eliminated before a lumbar radiculopathy can be confirmed. These include

- hip joint pathology (degenerative joint disease, avascular necrosis, synovitis, etc.)[602];
- meralgia paresthetica. This is syndrome, also known as Bernhardt–Roth syndrome, is characterized by pain

or dysesthesia in the anterolateral thigh, caused by entrapment of the lateral cutaneous (femoral) nerve of the thigh at the ASIS (see Chapter 5). Trummer et al.[603] reported that lumbar disk herniation could mimic meralgia paresthetica, and Kallgren and Tingle[604] noted that meralgia paresthetica could mimic lumbar radiculopathy because of the similarity of the symptoms.

- irritation of the spinal nerve root by osteophytic spurs;
- sacroiliac or pelvic dysfunction;
- intermittent claudication of the iliac or iliofemoral arteries;
- spondylolisthesis;
- lateral recess stenosis;
- muscle strain;
- stress fracture of the lumbar/thoracic vertebra (burst and compression);
- neoplasm;
- isolated peripheral nerve injury or neuritis; and
- diabetic amyotrophy, which is relatively uncommon but can occasionally be the presenting symptom of uncontrolled diabetes mellitus.[605]

The differential diagnosis can be aided by a description of the distribution of the patient's symptoms and the results of the physical examination.

High Lumbar Disk Lesions

From 1% to 11% of herniated disks originate from the L1–2, L2–3, or L3–4 levels.[606–608] Reduced motion and stress at the upper lumbar spine and the protective influence of the PLL may account for the disparity.[608]

CLINICAL PEARL

A number of studies have shown that with increasing age, lumbar disk herniation is more cranially localized so that higher level disk injuries are more common in advanced age.[609] Because of the nerve root anatomy previously discussed, a herniation at these high levels may occur without compromise to the nerve root, and may thus go undetected.

If symptoms are present, the high lumbar radiculopathy typically does not radiate pain down the back of the leg but, instead, causes an insidious onset of pain in the groin or anterior thigh that is often relieved in a flexed position and worsens with standing.[610] The superficial cremasteric reflex is also invariably present.[312]

The differential diagnoses for upper lumbar nerve root symptoms include spondylolisthesis and an infective cause, such as diskitis or an epidural abscess.

Third Lumbar Nerve Root Compression

The clinical findings with a lesion at this level may include

- pain in the midlumbar area, upper buttock, whole anterior thigh and knee, medial knee, and just above the ankle;
- dural signs of prone knee flexion and, occasionally, a positive SLR;
- significant motion loss of extension;
- slight weakness of iliopsoas and grosser loss of quadriceps;
- hypoesthesia of the medial aspect of the knee and lower leg; and
- absent or reduced patellar reflex.

TABLE 28-23 Common Radicular Syndromes of the Lumbar Spine

Disk Level	Nerve Root	Motor Deficit	Sensory Deficit	Reflex Compromise
L3–4	L4	Quadriceps	Anterolateral thigh	Knee Anterior knee Medial leg and foot
L4–5	L5	Extensor hallucis longus	Lateral thigh	Medial hamstrings Anterolateral leg Mid posterior (dorsal) foot
L5–S1	S1	Ankle plantar flexors	Posterior leg	Ankle Lateral foot

Data from American Medical Association. Guides to the Evaluation of Permanent Impairment. 5th ed. Chicago: American Medical Association; 2001.

Fourth Lumbar Nerve Root Compression

Approximately 40% of IVD impairments affect this level, about an equal amount as those that affect the L5 root.[29] A disk protrusion at this level can irritate the fourth root, the fifth root, or, with a larger protrusion, both roots (Table 28-23). The clinical findings with a lesion at this level may include

- pain located in the lumbar area or iliac crest, inner buttock, outer thigh and leg, and over the foot to the great toe;
- positive dural signs of SLR, bilateral and crossed SLR, and neck flexion (see Chapter 11)[308];
- marked lateral deviation of the lumbar spine and gross limitation of one side flexion (both common findings);
- weak dorsiflexion of the ankle;
- hypoesthesia of the outer lower leg and great toe;
- diminished tibialis posterior, patellar, and tibialis anterior muscle stretch reflexes.

Fifth Lumbar Nerve Root Compression

This level is affected as often as the fourth nerve root and is frequently compressed by the L4–5 disk as well as the L5–S1 disk (see Table 28-23). The clinical findings with a lesion at this level may include

- pain in the sacroiliac area, lower buttock, lateral thigh and leg, inner three toes, and medial sole of the foot;
- positive unilateral SLR and neck flexion[308];

- lateral deviation during flexion;
- weakness of peroneal, extensor hallucis, and hip abductor muscles;
- hypoesthesia of outer leg and inner three toes and medial sole; and
- diminished fibularis (peroneus) longus, Achilles, and extensor hallucis muscle stretch reflexes.

First, Second, and Third Sacral Roots

According to Cyriax, the first, second, and third sacral roots can be compressed by a fifth lumbar disk protrusion. The clinical findings with a lesion at the S1 level (see Table 28-23) may include[341]

- pain in the low back to buttocks to the sole of the foot and heel;
- limited SLR;
- weakness of the calf muscles, peronei, and hamstrings;
- atrophy of the gluteal mass (but weakness is not always detectable); and
- hypoesthesia in the outer two toes, outer foot, and outer leg as far as the lateral aspect of the knee.

With a second sacral root palsy, the signs are the same as for the first sacral nerve root, except that the fibularis (peroneal) muscles are spared, and the hypoesthesia ends at the heel. With third sacral root palsy, the SLR is generally normal, and no palsy is detectable. However, the patient may report pain in the groin, and pain down the inner aspect of the thigh to the knee.[593]

Fourth Sacral Nerve Root Compression

A lesion of this nerve root is always a concern, because a permanent palsy may lead to incontinence and impotence.[593,611] The clinical findings with a lesion at this level may include

- pain in the lower sacral, peroneal, and genital areas;
- saddle area paresthesia;
- no positive dural signs;
- possible gross limitation of all lumbar movements;
- bladder, bowel, or genital dysfunction; and
- positive superficial anal reflex and reduced anal wink.[312]

Vertical Prolapse (Schmorl's Node)

A Schmorl's node is the herniation of disk substance through the cartilaginous plate of the IVD into the body of the adjacent vertebra.[612] These vertical prolapses of the disk are often asymptomatic and occur as incidental findings on radiographs. Indeed, a chronic Schmorl's node has been reported to be the most common impairment of the IVD and of the whole spine.[613] Schmorl's nodes tend to be more common in men than in women, a factor attributed to the greater spinal loads in men.[612] Theories proposed to explain the pathogenesis of Schmorl's nodes include origins that are

- developmental, in which embryonic defects, such as ossification gaps, vascular channels, and notochord extrusion defects form points of weakness where Schmorl's nodes may occur.[22]
- degenerative, in which the aging process produces sites of weakness in the cartilaginous endplate, resulting in formation. of Schmorl's nodes.[613,614]
- pathologic, where diseases weaken the IVD and/or vertebral bodies.[615,616]
- traumatic, in which acute and chronic trauma destroy the cartilaginous end plates, resulting in disk herniation.

Although most orthopaedists accept that Schmorl's nodes occur because of trauma, no studies have shown a direct causal relation between a traumatic episode and the formation of an acute Schmorl's node.

Once the Schmorl's node has occurred, the subsequent proliferation of cartilage and reactive ossification may develop in the vicinity of the dislocated tissue.[135] This ossification encloses the dislocated tissue and segregates it from the spongiosa of the vertebral body. The formation of this cartilaginous cap, or calcification of the protrusion, may act to resist its expansion.[18]

Intervention

The natural history of radiculopathy and disk herniation is not quite as favorable as for simple LBP, but it is still excellent, with approximately 50% of patients recovering in the first 2 weeks and 70% recovering in 6 weeks.[617] Prognostic factors for a positive outcome with conservative intervention for lumbar disk herniation are depicted in Table 28-24.

CLINICAL PEARL

Intervention focuses on a return to normal activities as soon as possible, patient education and involvement, and therapeutic exercises.

Complete bed rest is not recommended in the first 4–6 weeks after onset of symptoms.[618,619] Surgery is often recommended after 4–6 weeks, if the symptoms persist, following MRI and CT scan findings.[620] However, of those who opt for surgery, 10–40% will complain of pain, motor dysfunction, or reduced activity of daily-living performance after surgery.[621,622] Ito et al.[620] showed that if patients with herniated lumbar disk could tolerate the symptoms of disk herniation for 2 months after onset of symptoms, it was possible to treat them with conservative approaches.[621] Using CT scan techniques, it was shown that 66% of herniated disk cases may normalize or recover either totally or partially with time and that large lumbar herniated nucleus propulsions can decrease and even disappear in some patients treated successfully with conservative care.[621,623] The McKenzie exercise program can be valuable to the overall intervention strategy and, if centralization of pain occurs, a good response to physical therapy can be anticipated.[293,509] In addition to the usual history taken, the McKenzie method makes particular inquiries regarding

- whether the symptoms are constant or intermittent;
- the topography of the symptoms; and
- whether the symptoms are better or worse with bending forward, sitting, rising from sitting, standing, walking, lying, rising from lying, when still, and/or on the move.

TABLE 28-24	Prognostic Factors of Positive Outcome with Conservative Intervention for Lumbar Disk Herniation
Outcome	**Factor**
Favorable	Absence of crossed SLR
	Spinal motion in extension that does not reproduce leg pain
	Relief or >50% reduction in leg pain within first 6 wks of onset
	Limited psychosocial issues
	Self-employed
	Educational level >12 yr
	Absence of spinal stenosis
	Progressive return of neurologic deficit within first 12 wks
Unfavorable	Positive crossed SLR
	Leg pain produced with spinal extension
	Lack of >50% reduction in leg pain within first 6 wks of onset
	Overbearing psychosocial issues
	Worker's compensation
	Educational level <12 yr
	Concomitant spinal stenosis
	Progressive neurologic deficit
	Cauda equina syndrome
Neutral	Degree of SLR
	Response to bed rest
	Response to passive care
	Gender
	Age
Questionable	Actual size of lumbar disk herniation
	Canal position of lumbar disk herniation
	Spinal level of lumbar disk herniation
	Lumbar disk herniation material

SLR, straight-leg raising.
Data from Saal JA. Natural history and nonoperative treatment of lumbar disc herniation. Spine. 1996;21:2S–9S.

Much of this information can be gained by asking the patient which activities of daily living produce the symptoms.

In cases of radiculopathy, the goal is to decrease radiating symptoms into the limb and, thus, to centralize the pain by using specific maneuvers or positions, such as the lateral shift correction (Fig. 28-8) VIDEO. Once this centralizing position is identified, the patient is instructed to perform these maneuvers repetitively or sustain certain positions for specific periods throughout the day.[597]

In addition, the patient is instructed in a lumbar stabilization program, in which neutral zone mechanics are practiced in various positions to decrease stress to the lumbosacral spine. Lumbar-stabilizing exercises have been recommended to improve lumbar function in patients with a low-back injury so that these patients may improve their activities of daily living.[621] It is theorized that these types of exercise may strengthen the stabilizer muscles, which control and limit the free movement of one vertebra on the other, thereby accelerating the recovery process of the herniated disk.

The intervention program is only as good as the concomitant home exercise program, and the clinician must continually monitor the home exercise program, evaluating the patient's knowledge of the exercises and upgrading the program when appropriate.

Surgery for Lumbar Radiculopathy

Several characteristics of patients with sciatica appear to predict the eventual need for surgery. These include a mentally demanding job (as opposed to a mentally nondemanding job or no job); a gradual onset of pain; an increase of pain with coughing, sneezing, or straining; and difficulty putting on socks or stockings.[624]

The aims of lumbar surgery for radiculopathy are to relieve pain and to restore neural function. Considerable literature reflects the evolution of lumbar disk surgery, and the most commonly performed neurosurgical procedure. Oppenheim and Krause in 1909 were the first to remove what was thought to be a lumbar spinal tumor (enchondroma, chordoma).[625] Other surgeries followed, leading to Mixter and Barr who systematized the diagnosis and operative treatment of lumbar disk prolapse in 1934.[594]

Lumbar disk herniation is one of the few causes of spinal pain that can be successfully treated surgically.[626] Several surgical options are available. The more common ones are described here.

Enzymatic Intradiskal Therapy (Chemonucleolysis)

Enzymatic intradiskal therapy is advocated as a minimally invasive, intermediate stage between conservative management and open-surgical intervention for a contained lumbar IVD prolapse.

Two enzymes are used in vivo: chymopapain and collagenase. The therapeutic concept behind the intradiskal therapy is to produce a decrease in the water-binding capacity of the polysaccharide side chains. This is supposed to result in a lowering of the pressure in the IVD, with a subsequent reduction in the size of the IVD protrusion and relief of the tension on the nerve root.

The success rate of chemonucleolysis with chymopapain or collagenase has been found to be approximately 72% and 52%, respectively.[627,628] However, the final outcome from chemonucleolysis, followed by surgery if chemonucleolysis fails, remains poorer than the outcome from primary diskectomy.[5] Consequently, although chemonucleolysis is an excellent procedure in principle, it is rarely performed. The complications associated with this procedure include allergic reactions, lumbar subarachnoid hemorrhage, and paraplegia.

Diskectomy

Diskectomy is a commonly performed surgical procedure in the general population, with high success rates reported in the literature.[629] There is now strong evidence on the relative effectiveness of surgical diskectomy versus chemonucleolysis versus placebo.[5]

Hemilaminectomy and Diskectomy

T ese diskectomies are usually approached posteriorly. Posterolateral diskectomy is used to treat herniated lumbar IVDs. T e aim of a diskectomy is to decompress the involved nerve root or roots while minimizing scar tissue formation and avoiding iatrogenic nerve damage.

Percutaneous Diskectomy

Percutaneous diskectomy is a minimally invasive procedure that uses a probe for automatic aspiration of the NP material from the IVD. Because the probe is inserted using a cannula, the procedure causes minimal damage to the muscles, bones, and joints of the back and no adherences in the epidural space. A short convalescence is, therefore, to be expected. T is procedure is indicated for patients with radicular pain, positive SLR, and positive neurologic signs and symptoms (atrophy, weakness, and sciatica) who have not responded to at least 6 weeks of conservative therapy. It also is advocated for patients with pure IVD herniation without lateral recess stenosis or any other additional factors. T ese factors include IVD fragments in the spinal cord, severe spinal arthritis, and LF hypertrophy.

Microdiskectomy

A microdiskectomy is designed to decompress neural tissues by removing the IVD material that is causing the compression and irritation of the nerve root. Microdiskectomy is reported to have a high success rate, more than 90% in some studies.[629] Following a diskectomy, patients are generally able to return to their previous levels of activity, including participation in recreational sports. T is surgery, however, can be associated with a long recuperation and a protracted period of disability.[630,631] Yilmaz et al.[632] investigated the efficacy of a dynamic lumbar stabilization exercise program in patients with a recent lumbar microdiskectomy. T e results of their randomized trial indicated that lumbar spine stabilization exercises under the direction of a physical therapist were superior to performing a general exercise program independently at home and to a control group of no prescribed exercises at 3 months.

Laser Diskectomy

As its name suggests, laser diskectomy uses a laser to remove diskal tissue and thereby alleviate the pressure on the nerve root. However, because it does not address the actual pathology, its success rate is dramatically inferior to that of standard diskectomy.[633]

Laminectomy

A laminectomy is defined as the removal of a lamina. A complete laminectomy involves the removal of the entire lamina, together with the spinous process and the LF caudal and cranial to the lamina. T e disadvantage of a complete laminectomy is that it may produce a destabilizing effect on the motion segment.[568]

Decompression

Decompression of the lumbar spine is defined as a laminectomy with partial facetectomy. Decompression may also be accompanied by partial laminectomy and canal enlargement, expansive lumbar laminoplasty, unilateral laminotomy for bilateral decompressions, or partial pediclectomy.

Fusion

T ere is little consensus among spine surgeons regarding the optimal indications for lumbar fusion surgery. Some surgeons believe that most patients with spinal lateral recess stenosis are appropriate candidates for spinal fusion. Others believe that most of these patients should undergo only a laminectomy because the degenerative changes that have occurred produce an inherent stability of the motion segment.

Controversy also exists regarding the use of fusion surgery versus nonsurgical approaches for degenerative disk disease with no herniation or lateral recess stenosis.[634] Spinal fusion is associated with wider surgical exposure, more extensive dissection, and longer operation times than laminectomy.

As an adjunct to the excision of recurrent lumbar IVD herniations, lumbar fusion provides several theoretical advantages[635]:

- reduction or elimination of segmental motion;
- reduction of mechanical stresses across the degenerated disk space;
- reduction of the incidence of additional herniation at the affected disk space.

Circumferential fusion has been advocated to improve fusion rates and clinical outcomes in the intervention of the lumbosacral spine. Circumferential lumbar fusion can be challenging, however, requiring either thecal sac retraction and bilateral facet disruption or a posterior lumbar interbody fusion.[636]

Alternative options have included either sequential anterior and posterior fusions or a posterior lumbar interbody fusion at the time of simultaneous posterolateral fusion. In 1982, Harms and Rolinger[636] suggested the placement of bone graft and titanium mesh, via a transforaminal route, into the disk space that previously had been distracted using pedicle screw instrumentation (transforaminal lumbar interbody fusion [TLIF]).

Other options for fusing the lumbar spine include bone grafting with a posterolateral approach without instrumentation (facet fusion or intertransverse fusion), a posterolateral approach with pedicle screws, or posterior lumbar interbody fusion or anterior lumbar interbody fusion (ALIF) with bone grafts, cages, or dowels.[635]

Complications of ALIF include postoperative ileus, vascular and visceral injury, retrograde ejaculation in males, and venous thrombosis.[637] Complications of TLIF include epidural bleeding, neural injury, postsurgical instability, epidural fibrosis, and arachnoiditis.[637] Most of the complications reported for the ALIF and TLIF procedures are approach rather than device related.

Lumbar Artificial Disk Replacement

T e use of lumbar artificial disk replacement for the treatment of symptomatic lumbar disk disease has recently been approved by the U.S. Food and Drug Administration (FDA). T e artificial disk is an alternative to fusion procedures and

offers the advantage in its ability to restore pain-free motion while protecting adjacent segments from increased loading and failure. Candidates for this procedure include patients who are 18–60 years and in whom nonoperative treatment for at least 6 months has failed and who have

- single level degenerative disk disease confirmed by MRI and diskography;
- no previous lumbar fusion;
- no instability, and;
- no extruded disk material.

Postsurgical Intervention

Patients who undergo spinal surgery may receive physical therapy as part of their rehabilitation. Although there is a large amount of information from evidence-based clinical practice guidelines for the management of many musculoskeletal conditions, there is relatively little information available on the physical therapy management of patients who have undergone spinal surgery.

The randomized controlled trials comparing various physical activity programs[465,638–640] have demonstrated the benefits of these programs. These benefits have included less pain and disability, improved ROM, and greater satisfaction with care.

Before the surgery, the patients may receive advice on spine care, postsurgical precautions, and instructions on basic exercises.

The postsurgical intervention following surgery is as varied as the number of types of surgery. The following are guidelines for postsurgical rehabilitation. The primary goals for the initial period following the surgery are

- reduction of pain and inflammation;
- prevention of postsurgical complications;
- protection of the surgical site;
- prevention of recurrent herniation;
- maintenance of dural mobility;
- improvement of function; and
- minimizing of the detrimental effects of immobilization.[641–646]
- early return to appropriate, functional activities. Patients usually are permitted to shower 1 week after the surgery.
- safe return to occupational duties. Patients with a sedentary occupation may return to work within 7–10 days after the surgery. Prolonged positions and postures are to be avoided.
- patient education on correct body mechanics and independent self-care.

The patient is given guidance on the gradual resumption of daily activities. Immobilization or prolonged rest should be avoided. Instead, the patient is encouraged to walk for short periods and distances several times a day.

Outpatient physical therapy, if appropriate, usually begins in the second or third week. The physical therapy examination includes

- a thorough history;
- inspection of the wound site;
- anthropometric data;
- postural examination; and
- neural examination, including neurodynamic mobility, and strength testing.

The components of the physical therapy intervention include a graded exercise program, with gentle ROM, submaximal isometrics, and arm and leg exercises as appropriate.

Additional interventions may include electrotherapeutic modalities, physical agents, and scar massage. Patient education is very important, particularly postural education and information on body mechanics.

Progressive strengthening exercises for the spinal stabilizers usually are initiated by the fourth postoperative week.

Cardiovascular conditioning exercises are introduced at the earliest opportunity based on patient tolerance. These include riding a stationary bicycle, using an upper body ergometer and a stair-stepper, and swimming in a pool. The sessions for these exercises are initially brief (5–10 minutes) and are gradually increased up to 30–60 minutes.

Activities such as jogging are usually permitted at 6–8 weeks if there is minimal pain. When the patient does resume these activities, they should be done in the morning hours when the IVD is maximally hydrated.[647] High-impact sports such as basketball and soccer are usually permitted after the 12th week.

Degenerative Spinal Stenosis

Degenerative spinal stenosis (DSS), a narrowing of the spinal canal, nerve root canal (lateral recess), or intervertebral foramen of the lumbar spine, and subsequent compression of the neural and vascular structures, is predominantly a disorder of the elderly—it is the most common diagnosis associated with lumbar spine surgery in patients older than 60 years.[648]

DSS is being diagnosed more frequently. The reasons for this are the widespread use of sophisticated noninvasive imaging techniques and the increasing elderly population. Lumbar spinal stenosis may be classified as central or lateral.[649]

- Central stenosis is characterized by a narrowing of the spinal canal around the thecal sac containing the cauda equina. The causes for this type of stenosis include facet joint arthrosis and hypertrophy, thickening and bulging of the LF, bulging of the IVD, and spondylolisthesis.
- Lateral stenosis is characterized by the encroachment of the spinal nerve in the lateral recess of the spinal canal or in the intervertebral foramen. Initially the depth of the canal that constituted narrowing was identified as an anteroposterior measurement,[650] but more recently the lateral width of the spinal canal has been studied.[345] The causes for this type of stenosis include facet joint hypertrophy, loss of IVD height, IVD bulging, and spondylolisthesis.

A compression of the nerve within the canal can result in a limitation of the arterial supply or claudication resulting from the compression of the venous return. Neurogenic claudication, or pseudoclaudication, can result in nerve root ischemia and symptomatic claudication, which is brought on by walking and relieved by sitting.[651] Compressive loading of the

spine can also exacerbate symptoms, such as those that occur with prolonged standing. Central stenosis, which can result in symptoms related to cauda equina compression, may occur more often with certain movements or changes in posture[652]:

- The length of the canal is shorter in lumbar lordosis than kyphosis.
- Extension and, to a lesser degree, side bending of the lumbar spine toward the involved side produces a narrowing of the canal.
- Flexion of the lumbar spine reverses the process, returning both the venous capacity and the blood flow to the nerve.

Both the history and the examination findings are very specific.

Patients with lumbar spinal stenosis who are symptomatic often relate to a long history of LBP. Unilateral or bilateral leg pain is usually a predominant symptom. Approximately 65% of patients with lumbar spinal stenosis present with neurogenic claudication.[651] Subjectively, the patient reports an increase in symptoms with lumbar extension activities such as walking, prolonged standing, and, to a lesser degree, side bending. On observation, the patient presents with a flattened lumbar lordosis.

The physical examination usually reveals evidence of reduced flexibility or shortening of the hip flexors (iliopsoas and rectus femoris). The hip extensor muscles (gluteus maximus and hamstrings) usually are lengthened. This is lengthening places them at a mechanical disadvantage, which leads to early recruitment of the lumbar extensor muscles and may lead to excessive lumbar extension.[653]

Therapeutic exercise is one of the numerous interventions that have been proposed for the conservative management of patients with lumbar spinal stenosis. Several authors advocate only the use of Williams flexion exercises because of the neuroforaminal narrowing that occurs with lumbar extension.[654,655] However, the prescribed program may need to be modified so that it does not exacerbate any coexisting orthopaedic conditions, such as osteoarthritis of the hips or knees while still being effective.[464] In a randomized clinical trial by Whitman et al.,[656] two physical therapy programs were compared for 58 patients with lumbar spinal stenosis:

- manual therapy (eclectic, consisting of techniques such as those described by Maitland,[657] Greenman,[332] and Whitman et al.[658]), body-weight-supported treadmill walking, and exercise group;
- lumbar flexion exercises, a treadmill-walking program, and subtherapeutic ultrasound group.

A greater proportion of patients in the first group reported recovery at 6 weeks compared with the flexion exercise and walking group ($p = 0.0015$), with a number needed to treat for perceived recovery of 2.6 (CI:1.8–7.8). At 1 year, 62% of the first group and 41% of the flexion exercise and walking group still met the threshold for recovery.[656]

Murphy et al.[659] performed a prospective cohort study of 57 consecutive patients with central, lateral, or combined central and lateral lumbar spinal stenosis. Patients were treated with lumbar thrust manipulation, nerve mobilization procedures (see Chapter 11), and exercise. The mean improvement in disability, as measured by the Roland-Morris Disability Questionnaire, was 5.1 points from baseline to discharge, and 5.2 points from baseline to long-term follow-up, satisfying the criteria for a minimally clinical important difference.[11]

Finally, Reiman et al.,[660] in a 2009 systematic review, recommended manual therapy techniques including thrust and nonthrust mobilization/manipulation to the lumbopelvic region for patients with lumbar spinal stenosis.

The therapeutic exercise progression is based on the underlying impairments and should include postural education; hip flexor, rectus femoris, and lumbar paraspinal stretching; lumbar (core) stabilization exercises targeting the abdominals and gluteals; aerobic conditioning; and positioning through a posterior pelvic tilt. There is some controversy as to whether the hamstrings should be stretched, as lengthening of these muscles may allow the pelvis to rotate anteriorly, resulting in an increased lordosis and further stenosis.

Failure to respond to a conservative approach is an indication for nerve root and sinuvertebral nerve infiltration, or surgical decompression of the nerve root if nerve root infiltration fails.

Zygapophyseal Joint Dysfunction

The term Facet joint syndrome refers to a pain-provoking dysfunction of the zygapophyseal joint.[132] This is pain is the result of a lesion to the joint and its pain-sensitive structures. Zygapophyseal movement dysfunctions can result from a hypomobility or a hypermobility instability (see "Clinical Instability of the Lumbar Spine" section).

Hypomobility

Hypomobility in the lumbar spine can have a variety of causes including ligament tears,[661] muscle tears or contusions,[662] lumbago,[341] intraarticular meniscoid entrapment,[576] zygapophyseal joint capsular tightness, and zygapophyseal joint fixation or subluxation.[663]

Theoretically, the signs and symptoms that present with a hypomobility include unilateral LBP that is aggravated with certain movements. Given that the joint is only capable of flexion and extension movements, it is assumed that flexion or extension movements can provoke pain, particularly at the end of these ranges. These movements are tested with active ROM and the combined motion tests and confirmed with the position tests of the PPIVM and PPAIVM tests.[394]

Hypomobility of the zygapophyseal joint can have an extraarticular, periarticular, or pathomechanical cause, with the distinction being made by the results of the end-feel obtained by the clinician during the PPIVM and PPAIVM tests.[394]

- Extraarticular. Decreased range with the PPIVM, but normal PPAIVM.
- Periarticular. Restriction of range in both PPIVM and PPAIVM tests, with a hard capsular end-feel.
- Pathomechanical. Restriction of range in both PPIVM and PPAIVM tests, with an abrupt, slightly springy end-feel.

The conservative intervention for a zygapophyseal dysfunction includes specific joint mobilizations, postural education, correction of muscle imbalances, and core stabilization exercises.

CLINICAL INSTABILITY OF THE LUMBAR SPINE

T ere is considerable controversy as to what, exactly, constitutes spinal instability. Traditionally, the radiographic diagnosis of increased translation or angulation of a spinal segment during flexion–extension or side bending in patients with chronic LBP was considered to be one of the most obvious manifestations of lumbar instability.[185,664] However, lumbar segmental instability in the absence of radiographic findings has also been cited as a significant cause of chronic LBP.[665,666] T e limitation in the clinical diagnosis of lumbar segmental instability lies in the difficulty of accurately detecting abnormal or excessive intersegmental motion, either radiographically or through palpation.[333] One of the limitations in the radiographic diagnosis of clinical instability is that the testing is static and assesses the spinal segment mobility at its end of range (outside the neutral zone of motion), rather than accurately assessing the functional control of the spinal segment within its neutral zone.[185] Hypermobility, a close relative of instability, is usually the most difficult movement impairment to diagnose in the spine because it is not a matter of stiffness, but rather of a relative degree of looseness.[394] Because of a lack of sensitivity and specificity of any one test, or combination of tests, to accurately identify clinical instability, its diagnosis requires the presence of a concurrent number of diagnostic criteria based on findings from the subjective and physical examination.[185]

T e following clinical findings (anywhere in the spinal joints) may indicate the presence of instability and its pertinence to the presenting complaints of the patient:

- back pain that is most commonly described as recurrent, constant, catching, locking;
- repeated unprovoked episode(s) of feeling unstable or giving way, following a minor provocation;
- inconsistent symptomatology. T e most frequently reported aggravating postures are sustained sitting, prolonged standing and semi flexed postures.[667] T e most common aggravating movements are typically forward bending, sudden, unexpected movements, returning in an upright position from forward bending, lifting, and sneezing.[667]
- minor aching for a few days after a sensation of giving way;
- compression symptoms (vertebrobasilar, spinal cord), which are not associated with a history of an IVD herniation or stenosis;
- consistent clicking or clunking noises;
- protracted pain (with full ROM);
- creases posteriorly or on the abdomen (spondylolisthesis);
- spinal ledging;
- spinal angulation on full ROM;
- inability to recover normally from full ROM, commonly flexion; and
- excessive active ROM. Active spinal movement, commonly reveals good ranges of spinal mobility but with aberrant quality of motion commonly associated with a sudden acceleration, hesitation, or lateral movement within the midrange of spinal motion.[185]

Intervention

Instability of the spine is perhaps the most difficult of the motion impairments to treat, which makes prevention extremely important. A stiff or jammed joint is a relatively simple problem that requires selecting and applying a mobilization or manipulation technique. Instability is a permanent, or at best, a semi-permanent state. T e intervention for a hypermobility or instability involves the removal of any abnormal stresses from the joint. If the underlying cause of the articular hypermobility is deemed to be a localized joint hypomobility, then this dysfunction must logically be dealt with first using joint mobilizations or stretching techniques.[394] T e techniques to increase joint mobility and the techniques to increase soft-tissue extensibility are described later in "T erapeutic Techniques" section. Following the diagnosis, and the correction of any articular hypomobility, the focus shifts to retraining muscles that are involved in the dynamic stabilization and segmental control of the spine.

Whereas conventional exercises generally work to increase the strength of the global muscles, a combined approach, which aims to improve the dynamic stability role of the segmental muscles during functional postures and movements in conjunction with the focus on the global muscles is recommended. T is approach has proven beneficial in a number of LBP conditions and can also be incorporated as part of a low-back injury prevention program. For example, O'Sullivan et al.[551] have demonstrated decreased pain and disability in patients with chronic LBP, who have a radiologically confirmed diagnosis of spondylolysis or spondylolisthesis.

While stressing the low-back tissues may enhance their health, too much loading can be detrimental. An assessment and rehabilitation strategy for the core is based on dysfunction in the local muscles (the transversus abdominis, and the multifidi). Choosing the optimal exercise requires judgment based on clinical experience and scientific evidence.[494] Training should begin in non–weight-bearing positions depending on patient response, in prone lying, in the quadruped position, or in supine lying before progressing to weight-bearing postures. It is important to note that the quadruped position has a significantly higher COG and smaller base of support (BOS) than the prone position, making it a more challenging position. Initially, the exercises prescribed are those that were found to provide relief during the examination. Usually, either flexion or extension movements demonstrate benefit. Contractions initially are held for 5 seconds and gradually are increased to 60 seconds. Training is performed a minimum of once a day for 10–15 minutes, with emphasis on proper cocontraction of the local muscle system. Depending on the severity of the condition, this range may initially be small, permitting only upper or lower extremity motions and gentle isometrics of the spinal muscles.

- ***T**ransversus abdominis (**T**rA) exercise.* T is exercise, also known as the abdominal drawing-in maneuver, is the first exercise taught to the patient as it activates local muscles without activation of the global muscles.[521] T e

FIGURE 28-55 Abdominal drawing-in with palpation.

TrA exercise has been reported to result in preferential activation of the IO and TrA, with little contribution by the rectus abdominis, and minimal lumbar spine motion in the pain-free population.[113,668] The patient, placed in hook-lying (with knees 70–90 degrees and feet resting on the floor), quadruped, prone, or the semireclined position (based on comfort), is asked to take a relaxed breath in and out and then draw the waist-line in (toward the spine) without taking a breath.[420] The contraction must be performed in a slow and controlled manner. Assessment of optimal recruitment of the TrA can be challenging as it is not possible to directly palpate the TrA just distal to the ASIS and lateral to the rectus abdominis (Fig. 28-55) through the IO muscle.[378] Consequently, muscle palpation of the TrA has been shown to have moderate reliability[378] but is dependent on the skill of the examiner, and its validity has not been established.[420] When performed correctly, the clinician should feel flat tension of the muscle, rather than a bulge if the IO contracts, and should see no substitute patterns (no movement of the pelvis, no flaring or depression of the lower ribs, no inspiration or lifting of the rib cage, no bulging out of the abdominal wall, and no increased pressure through the feet).[79,114,669] Activation of the pelvic floor muscles or multifidus can be used to initiate activity in the TrA. Once the technique is successfully learned, the patient is encouraged to perform the exercise while in the sitting and standing positions while self-palpating.[79,114,420,669] The use of a biofeedback unit, such as the stabilizer (Chattanooga Group, Hixson, TN) (Fig. 28-56), which consists of a pressure bladder that is placed between the lumbar spine and the bed, on which the patient is in a supine position, and a pressure gauge, similar to a sphygmomanometer, that detects movement of the lumbar spine via changes in pressure applied to the air-filled bladder. Theoretically, correct performance of the abdominal drawing-in maneuver will not result in pressure fluctuations, thus indicating a stable lumbar spine. In contrast, individuals who are not able to appropriately utilize the TrA must rely on superficial muscles, such as the rectus abdominis and external oblique, to maintain spine stability, which is indicated by an increase in pressure due to flattening of the lumbar spine against the pressure bladder.[670] However, a 2011 systematic review on the properties of the pressure biofeedback unit concluded that the most important question regarding the units used in clinical practice has yet to be answered, that is, its ability to assess the activation of the TrA.[380] A more recent study by Grooms et al.[671] reported that successful completion on pressure biofeedback does not indicate high TrA activation, but that unsuccessful completion may be more indicative of low TrA activation, which suggests that the pressure test is likely of minimal value to detect TrA activation.

FIGURE 28-56 The stabilizer biofeedback unit.

- **Abdominal bracing.** McGill[201] advocates an exercise progression that incorporate all of the core muscles using bracing of the spine, which has been shown to activate all three layers of the abdominal musculature, not just the TrA. This approach is based on studies of the assessment of muscular contributions to stabilization during a variety of exercises positions, which have found that a muscle's relative contribution to spine stability is dependent on the activity.[672,673] For the preliminary exercise in this progression, the patient is positioned in supine with the hips and knees flexed with the feet resting on the bed.[201,420] The patient is asked to activate the abdominal musculature and back extensors simultaneously so that both areas feel firm. The abdominal bracing contraction has been found to be superior to the TrA exercise for enhancing stability.[201]
- **Multifidus activation.** The patient lies in the prone or side-lying position. The clinician uses the thumbs or index fingers to palpate immediately lateral to the spinous processes of the lumbar spine, and the patient is asked to bulge the muscle out against the palpating digits (Fig. 28-57). Emphasis is placed on slow, and gentle tension or swelling of the muscle as the goal is to increase control, not strength. So that the patient can practice at home, a small piece of tape can be placed on the skin over the muscle to help patients find the correct level easily.

Pelvic Floor Muscle Activation

The pelvic floor muscles can be activated in isolation or in conjunction with activation of the TrA or multifidus. If activated in isolation the following instruction is given: "Contract as if you are stopping the flow of urine while you attempt to pull the ischial tuberosities together."

Once these techniques are mastered in the position of comfort, they are performed with the head, and lower and upper extremity movements (arm raises, bent leg raises) to improve muscular endurance depending on the emphasis of the intervention.[212,674]

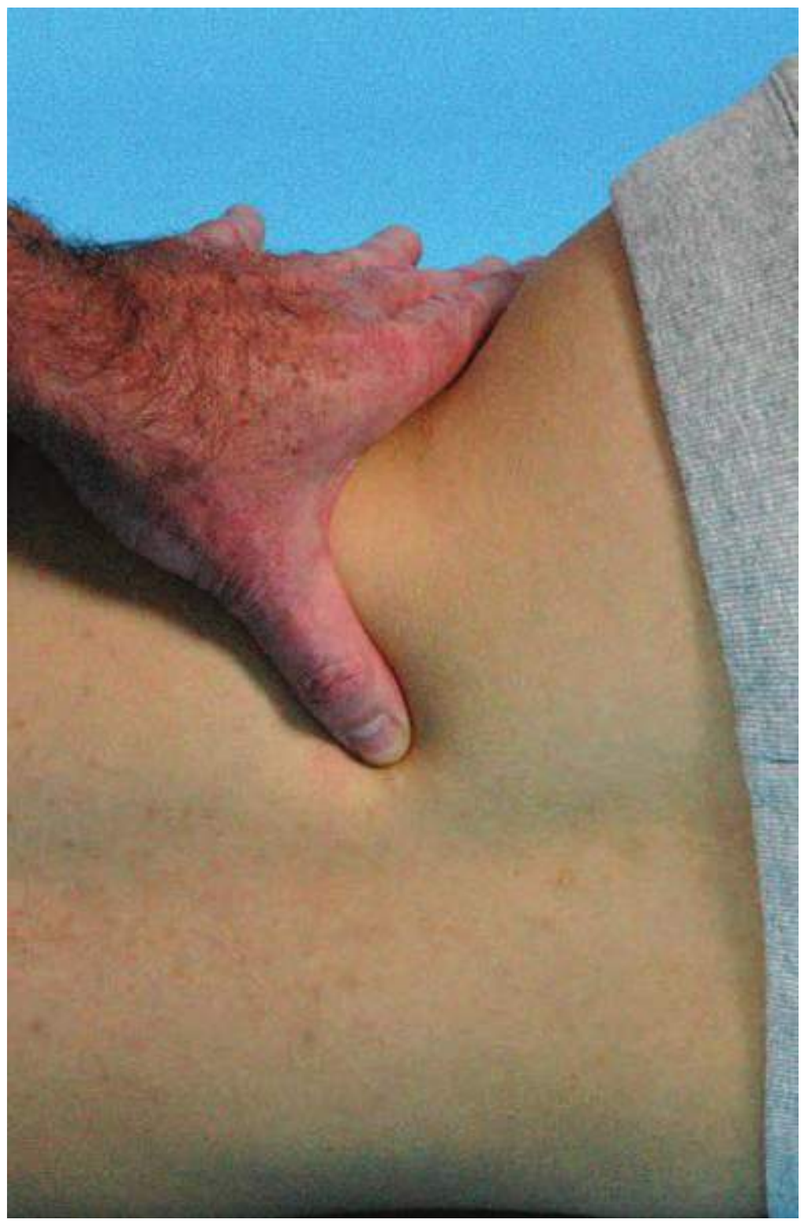

FIGURE 28-57 Multifidus activation.

Diaphragm Activation

The patient is in the supine hook-lying, side-lying, or prone over a pillow to relax the paraspinal muscles and place the patient's lumbar spine in neutral. The patient is asked to focus on active inspiration using the contraction of the diaphragm (movement of the abdominal wall and basal rib cage) and relaxed expiration. Manual contact by the clinician can be used to encourage basal rib cage expansion.

Once these muscle activations can be performed in isolation and in the controlled position, the clinician then attempts to promote static coordination between the local and global muscles using the following progression:

- **Extremity loading:** Superimposing upper and then lower extremity movements while maintaining the position of the spine and pelvis (Fig. 28-58).
- **Rhythmic stabilization:** The clinician applies various low forces to the body with slow alternations while the patient maintains a neutral position. These techniques are performed in supine initially and then in sitting.
- **Unstable base:** The patient holds the neutral spine position during extremity loading and rhythmic stabilization.
- **Functional movements:** The patient holds the neutral spine position during a variety of functional activities, such as walking, weight shifting, and trunk rotations.

A variety of exercises that emphasize specific muscle groups, depending on the clinical findings, can be introduced. All of the following exercises are superimposed on the neutral spine (midrange or functional position), making sure the patient maintains control while performing the exercises:

Emphasis on Abdominals[675]

- Bent-leg *f*all out. The patient is placed in the supine hook-lying position (knees at 90 degrees of flexion) and is asked to separate the knees while preventing pelvic rotation (Fig. 28-59).
- Progressive limb loading. From the supine hook-lying position the patient is asked to do the following:
- lift one of the legs to 90 degrees of hip and knee flexion (Fig. 28-60), then
- move the heel of the raised leg away from the body to extend the knee (Fig. 28-61), and then finally
- to lift the straight leg to 45 degrees (Fig. 28-62).

The exercise is then repeated using the other leg.

FIGURE 28-62 Progressive limb loading 3.

FIGURE 28-63 Progressive limb loading 4.

FIGURE 28-64 Progressive limb loading 5.

FIGURE 28-65 Progressive limb loading 6.

The exercise progression then follows a series of levels of increasing difficulty while performing the same three methods of progressive limb loading:

- The opposite leg is held at 90 degrees of hip flexion using both upper extremities (Fig. 28-63).
- Both legs perform the series of progressive limb loading simultaneously (Fig. 28-64).

At this stage, external resistance in the form of weights, elastic resistance, or pulleys can be added for strengthening.

- The opposite leg is held at 90 degrees of hip flexion with no upper extremity assistance (Fig. 28-65).
- Abdominal crunch. The patient lies in the supine position with the knees flexed to approximate 90 degrees and the feet resting on the table. The patient folds his or her hands across the chest. The patient is asked to perform the abdominal drawing-in maneuver, and then to raise the head and shoulders upward until the shoulder blades clear the table (Fig. 28-66). This position is held for

FIGURE 28-66 Abdominal crunch.

FIGURE 28-68 Prone progression.

approximately 5 seconds before the patient returns to the starting position.

Flexion Endurance Test. McGill[201] advocates the enhancement of muscular endurance of the core, once the patient has progressed sufficiently to tolerate the exercises. T ere are three muscular endurance tests for the core with each being measured in seconds until failure: the flexion endurance test, the back extensor test (see later), and the lateral musculature test (see later). T ese assessments evaluate the isometric strength of the various regions of the core under the premise that muscle endurance, rather the muscle strength, is a more important factor in core stability. For the flexion endurance test, the patient's feet are secured on the bed and patient moves into the "up" position of the standard sit-up (at approximately 60 degrees from the tabletop), with the hips and knees in a 90–90 degrees alignment, and with the arms folded across the chest T e patient can also be reclined against a bolster (Fig. 28-67A). Keeping the arms folded across the chest, the patient maintains the position for as long as possible. If a bolster is used, the test begins as soon as the bolster is removed (Fig. 28-67B).

Emphasis on the Trunk Extensors.[675] T e following exercises are performed with the patient lying in prone position:

- extend one lower extremity (Fig. 28-68);
- extend both lower extremities (Fig. 28-69); and
- lift the head, arms, and lower extremities (Fig. 28-70).

For patients with limited lumbar extension, or those with increased symptoms with lumbar extension, a small pillow can be placed under the hips in prone for the starting position, and the patient can lift the upper and lower extremities to the neutral position of the lumbar spine.

At this stage, external resistance in the form of weights, elastic resistance, or pulleys can be added for strengthening.

T ese exercises are then performed in the quadruped position and include the following progression:

- flex one upper extremity (Fig. 28-71);
- extend one lower extremity (Fig. 28-72); and
- flex one upper extremity and extend the contralateral lower extremity (Fig. 28-73).

Back Extensor Endurance Test. T e second endurance test advocated by McGill[201] is designed to test the endurance of the back extensors. T e patient is positioned in prone with the lower body braced against it using straps or the clinician's body weight. T e patient's torso is positioned off the table, above the ASIS (Fig. 28-29A–B) T e upper extremities and trunk can be supported on a chair before the start of the test. When the patient is ready, the chair is removed, and the patient attempts to maintain the torso approximately parallel to the ground for as long as possible while keeping the arms placed across the chest.

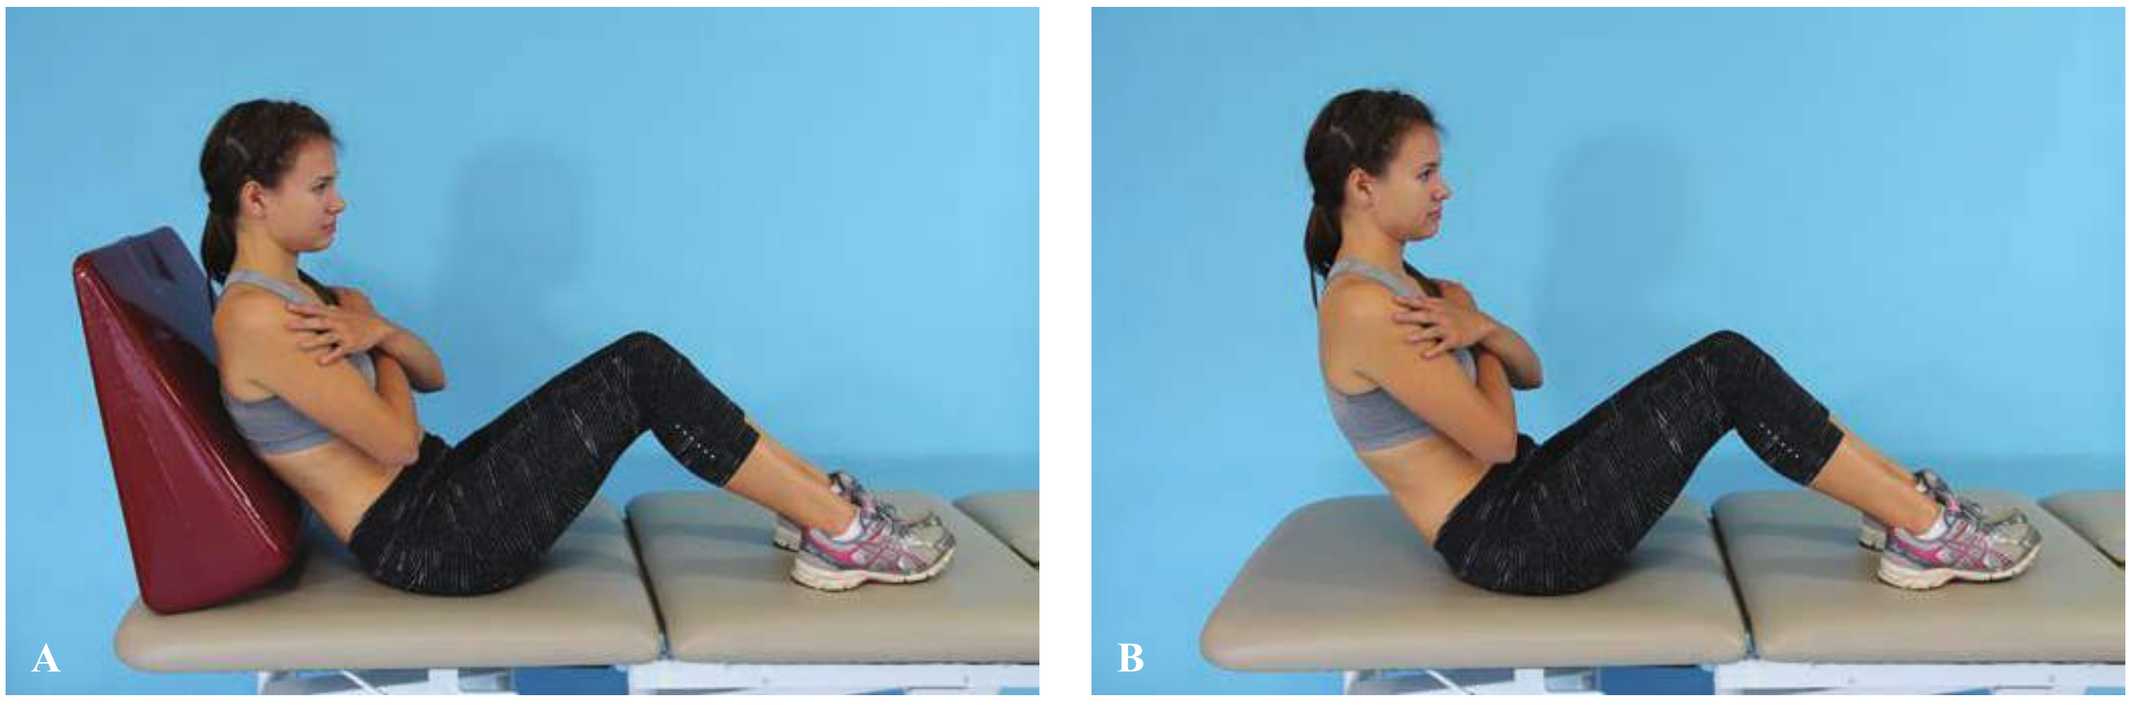

FIGURE 28-67 A,B: Abdominal sit-back.

FIGURE 28-69 Prone progression 2.

FIGURE 28-70 Prone progression 3.

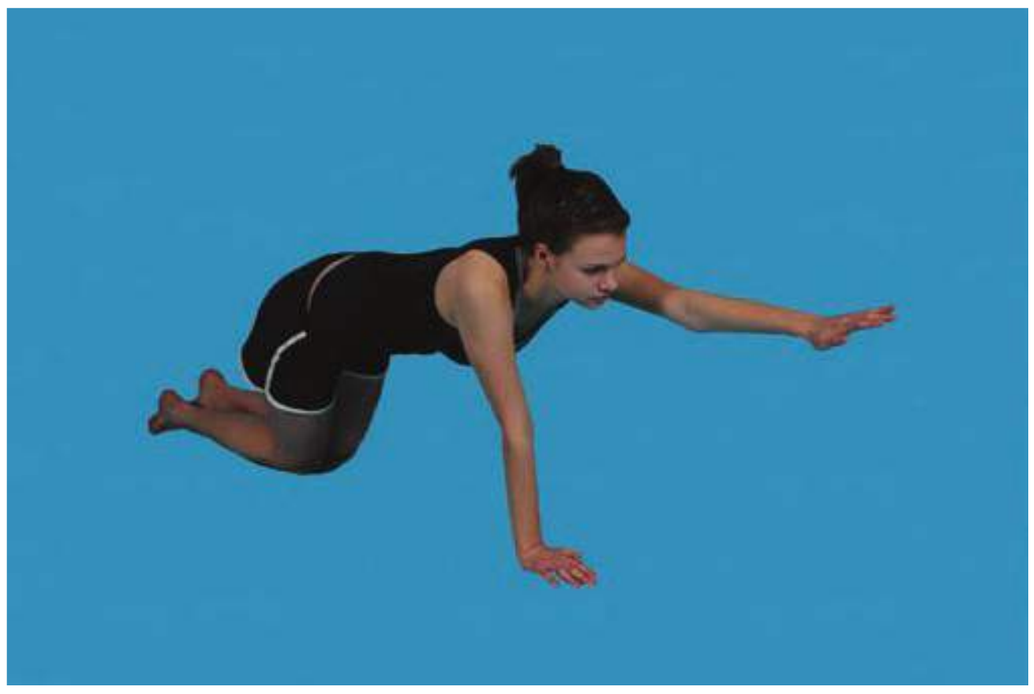

FIGURE 28-71 Quadruped progression 1.

Emphasis on the Lateral Stabilizers. T ese exercises are performed in the side-lying position and include the following progression

- side plank with hips on bed (Fig. 28-74);
- side plank (Fig. 28-75);
- side plank with arm extended (Fig. 28-76);
- side plank with hip abduction (Fig. 28-77); and
- side plank with inward roll (Fig. 28-78).

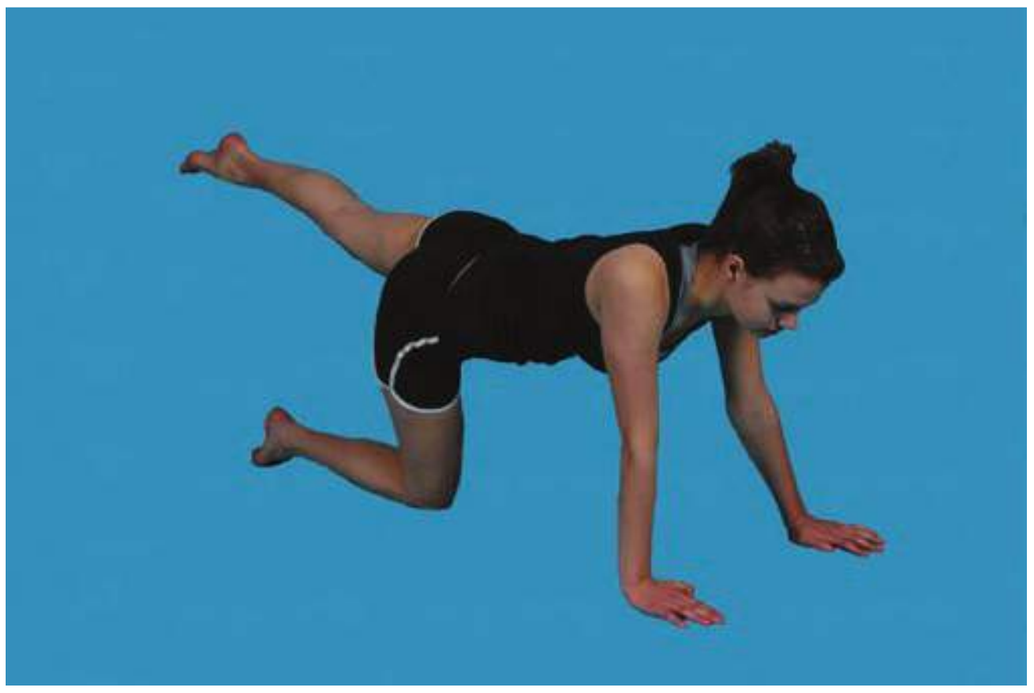

FIGURE 28-72 Quadruped progression 2.

FIGURE 28-76 Side-lying progression 3.

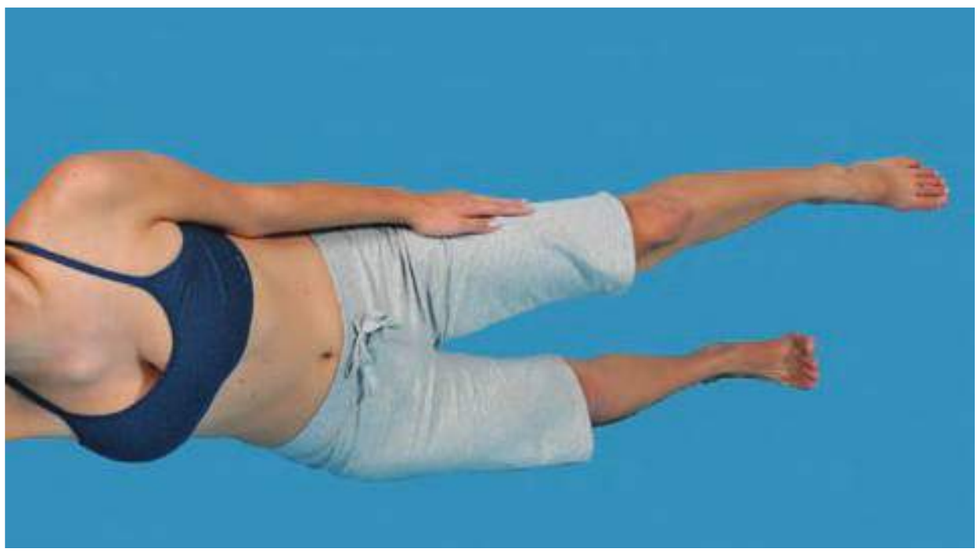

FIGURE 28-77 Side-lying progression 4.

FIGURE 28-78 Side-lying progression 5.

FIGURE 28-80 Bridging progression 1.

Lateral Musculature Test. The third endurance test advocated by McGill[201] is designed to test the endurance of the lateral muscles of the core. The patient is positioned in side lying with the legs extended in line with the torso and with one foot positioned in front of the other, or on top of the other (Fig. 28-79A). The hand of the non–weight-bearing upper extremity is placed on the opposite shoulder or on the hip. When the patient is ready, he or she places one elbow, flexed 90 degrees, below the shoulder and maintains the position for as long as possible (Fig. 28-79B). According to McGill,[201] the flexion or lateral endurance scores should be less (in terms of the time that the position is able to be maintained) than the extension score (flexion/extension <1.0 and lateral/extensor <0.75).

Emphasis on Function

- Bridging. The patient is positioned supine, with the arms by the sides. The patient is asked to keep the knees bent and feet flat, and to lift the buttocks from the floor (Fig. 28-80). The exercise can be made more challenging by having the patient squeeze a ball with their thighs while performing the bridge (Fig. 28-81).
- Bridging with feet on a ball, knees bent (Fig. 28-82).
- Bridging with feet on a ball, knees straight (Fig. 28-83).
- Bridging with shoulders on a Swiss ball (Fig. 28-84).

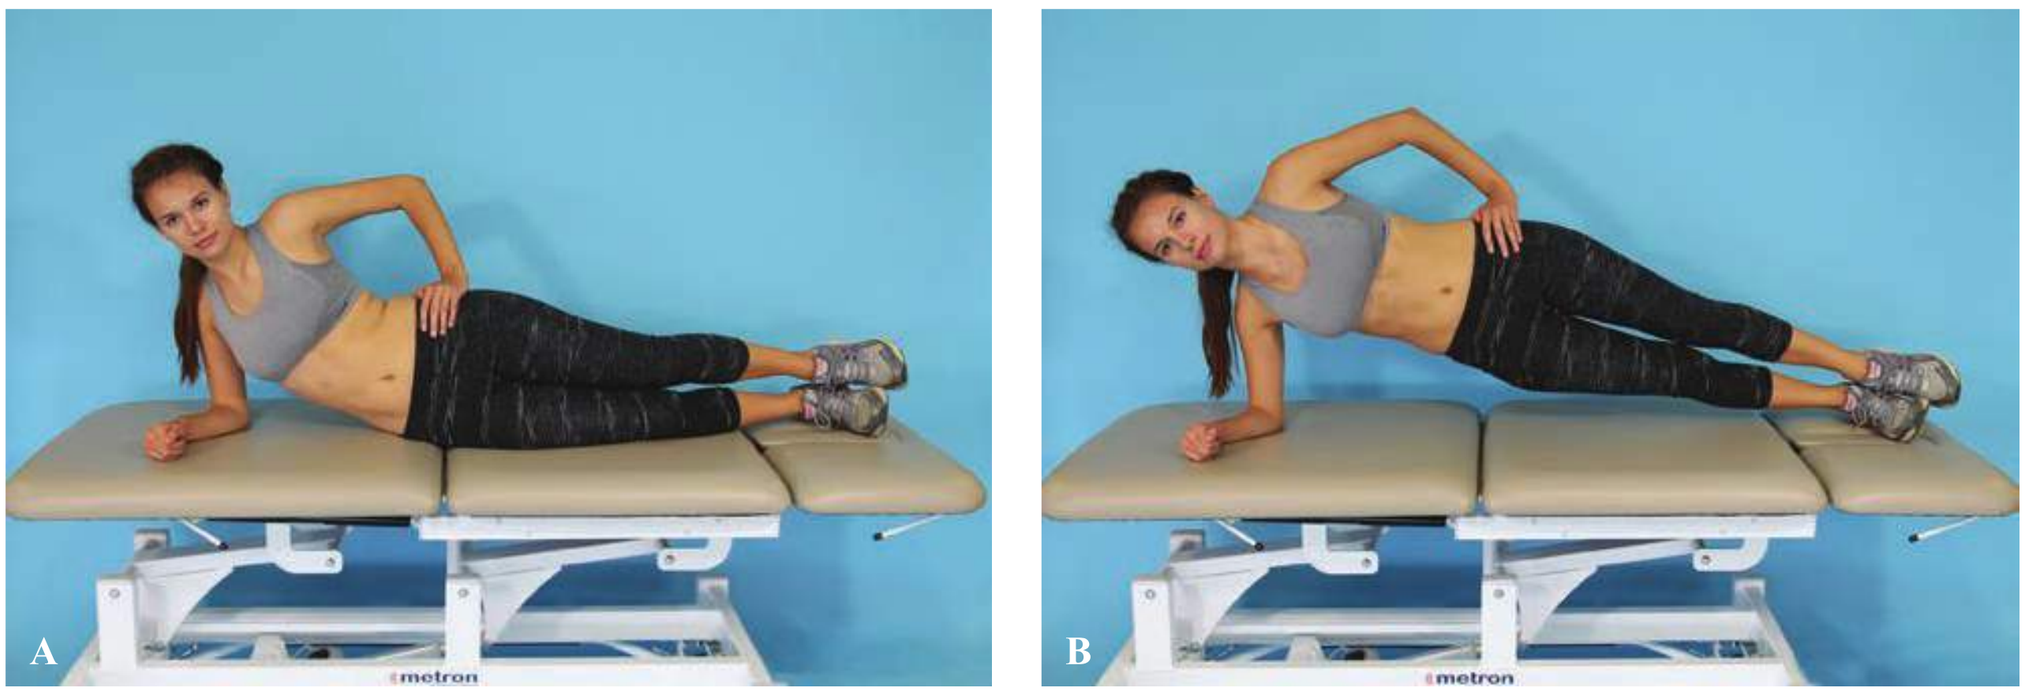

FIGURE 28-79 Lateral musculature test. A: Start position. B: End position.

FIGURE 28-81 Bridging progression 2.

FIGURE 28-82 Bridging progression 3.

FIGURE 28-83 Bridging progression 4.

- Wall slides. With the back against a wall, the patient is asked to perform a squat and then return to standing, while maintaining the neutral zone throughout the exercise. Modifications to this exercise include
  - a medicine ball is placed between the patient's knees.
- Forward lunge. While maintaining the neutral zone throughout the exercise, the patient is asked to step forward with one leg, and lower the opposite knee toward the ground. Hand weights, elastic resistance, or dumbbells (Fig. 28-85) can be used to make the exercise more challenging.
- Backward lunge. While maintaining the neutral zone throughout the exercise, the patient is asked to step backward with one leg, and lower the same knee to the ground, before returning to the starting position. Hand weights, elastic resistance, or dumbbells can be used to make the exercise more challenging.
- Chop and lift. The chop and lift motions are excellent at recruiting the lumbar stabilizers for mobility or stability. These motions can be performed in half kneeling (Fig. 28-86), tall kneeling (Fig. 28-87), or standing (Fig. 28-88). In contrast to the standing posture that

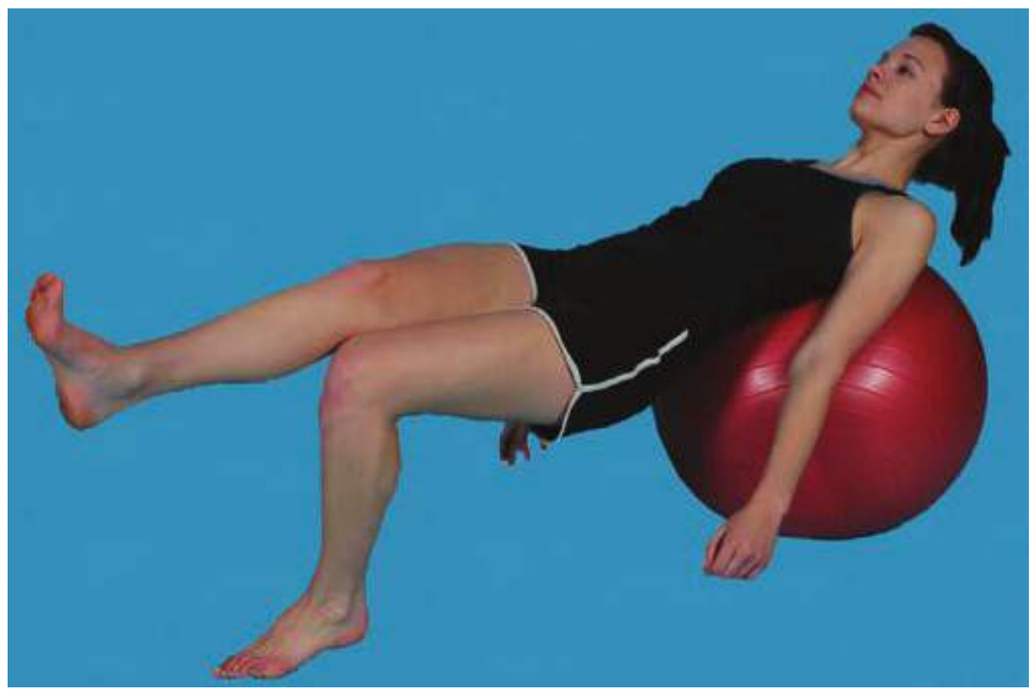

FIGURE 28-84 Bridging progression 5.

FIGURE 28-85 Forward lunge.

FIGURE 28-86 Chop and lift in half-kneeling.

FIGURE 28-88 Chop and lift in standing.

offers a wide, adaptable BOS and can utilize all portions of the lower extremity kinetic chain, the kneeling position provides a narrow BOS, rendering distal portions of the kinetic chain unable to assist in corrected movements.[676] Tall kneeling creates a challenge to balance reactions in the anterior and posterior directions, whereas half kneeling creates a challenge to balance reactions laterally.[676]

FIGURE 28-87 Chop and lift in tall-kneeling.

Kibler et al.[677] recommend evaluating core stability in functional positions by testing in multiple planes of motion, closed versus open chain testing, and concentric versus eccentric muscle contractions (one-legged standing balance, single leg squat, and single leg standing with three-plane excursion). Deficiencies in core stability include using the arms for balance, excessive trunk motion, or excessive knee valgus moment during the one-legged standing balance or single leg squat.[677] T e three-plane excursion test evaluates the ability of the core and spinal muscles to maintain control during sagittal, frontal, and transverse plane movements by placing an individual approximately 8 cm away from a wall and asking him or her to move in all three planes to produce a controlled touch of the wall with the head or shoulder.[677]

Emphasis on Athletic Performance

- Hip thrusts. T e patient is positioned supine, with the hips and knees flexed to approximately 90 degrees and the arms by the sides (Fig. 28-89). From this position, the patient is asked to perform an abdominal hollowing and lift the pelvis off the bed, while maintaining the hip and knee positions. Once the patient is able to do this exercise independently, the exercise can be performed with the hips flexed to 90 degrees and the knees extended (Fig. 28-90).
- Rotational partial sit-up. T e patient is asked to lift the chin toward the chest. T e patient is then asked to attempt to lift the right shoulder up from the table, while twisting the trunk to the left and touching the outside of

FIGURE 28-89 Hip thrusts.

the opposite knee (Fig. 28-91), before slowly lowering the shoulder to the table.

- Reverse curl-up. The patient lies in the supine position, with the legs bent at the knees and the feet flat on the floor. The arms are by the sides. The patient is asked to raise the feet off the bed until the thighs are flexed

FIGURE 28-90 Hip thrust exercise with resistance.

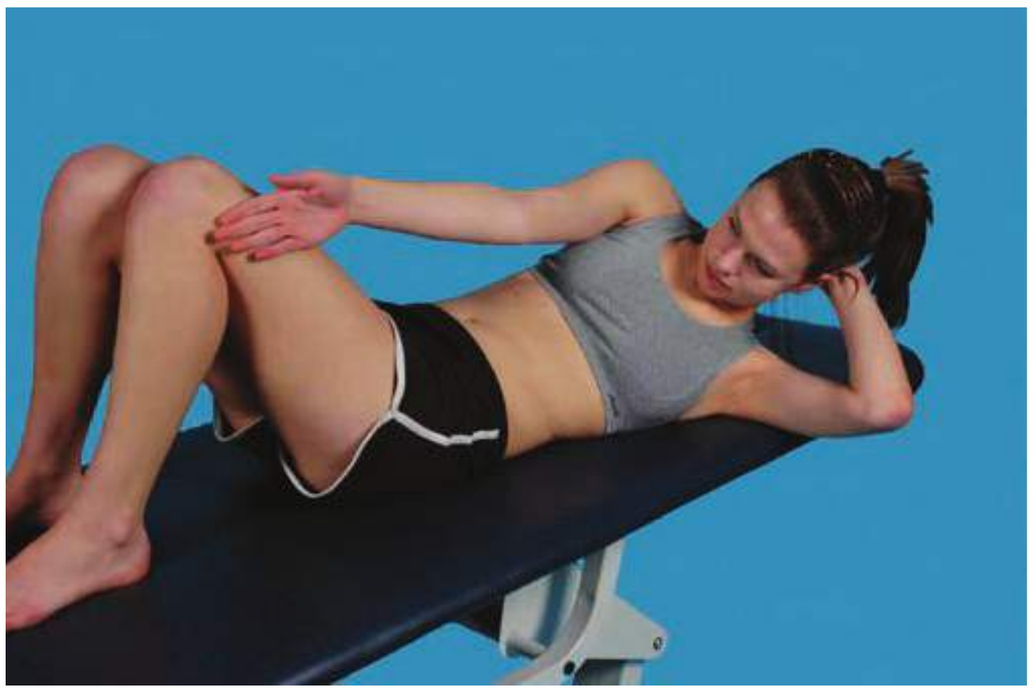

FIGURE 28-91 Rotational partial sit-up.

(Fig. 28-92). This is the start position. From this position, the patient is asked to raise the pelvis up and toward the shoulders, keeping the knees bent tightly, until the knees are as close to the chest as possible. The patient is allowed to push down on the bed with the hands. After holding this position for 2–3 seconds, the patient returns to the start position.

- Superman. The patient lies in the prone position, with the arms overhead and knees straight, the patient is asked to raise both arms and legs toward the ceiling, while keeping the head raised off the table (Fig. 28-93).
- Prone plank (Fig. 28-94). This exercise can be made more challenging by asking the patient to raise one upper extremity at a time, one lower extremity at a time, or opposite upper extremity and lower extremity simultaneously.
- Prone lying on a Swiss ball, hands touching the *floor* (Fig. 28-95). This can be progressed to push-ups with the legs on a chair, and to walking in circles around the Swiss ball using only the hands.
- Swissball stir the pot (Fig. 28-96A–B).

FIGURE 28-92 Reverse curl up.

FIGURE 28-93 Superman position.

FIGURE 28-94 Prone plank.

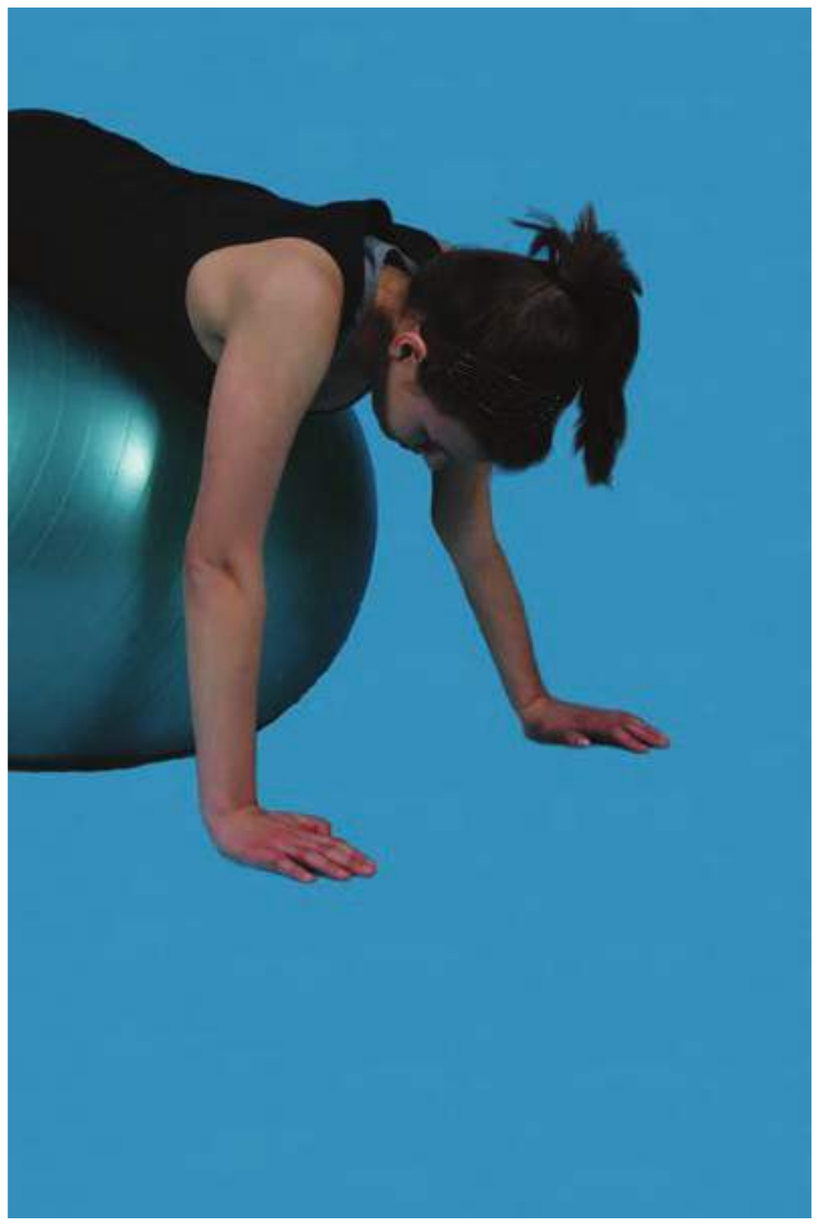

FIGURE 28-95 Prone lying on a Swiss ball, hands touching floor.

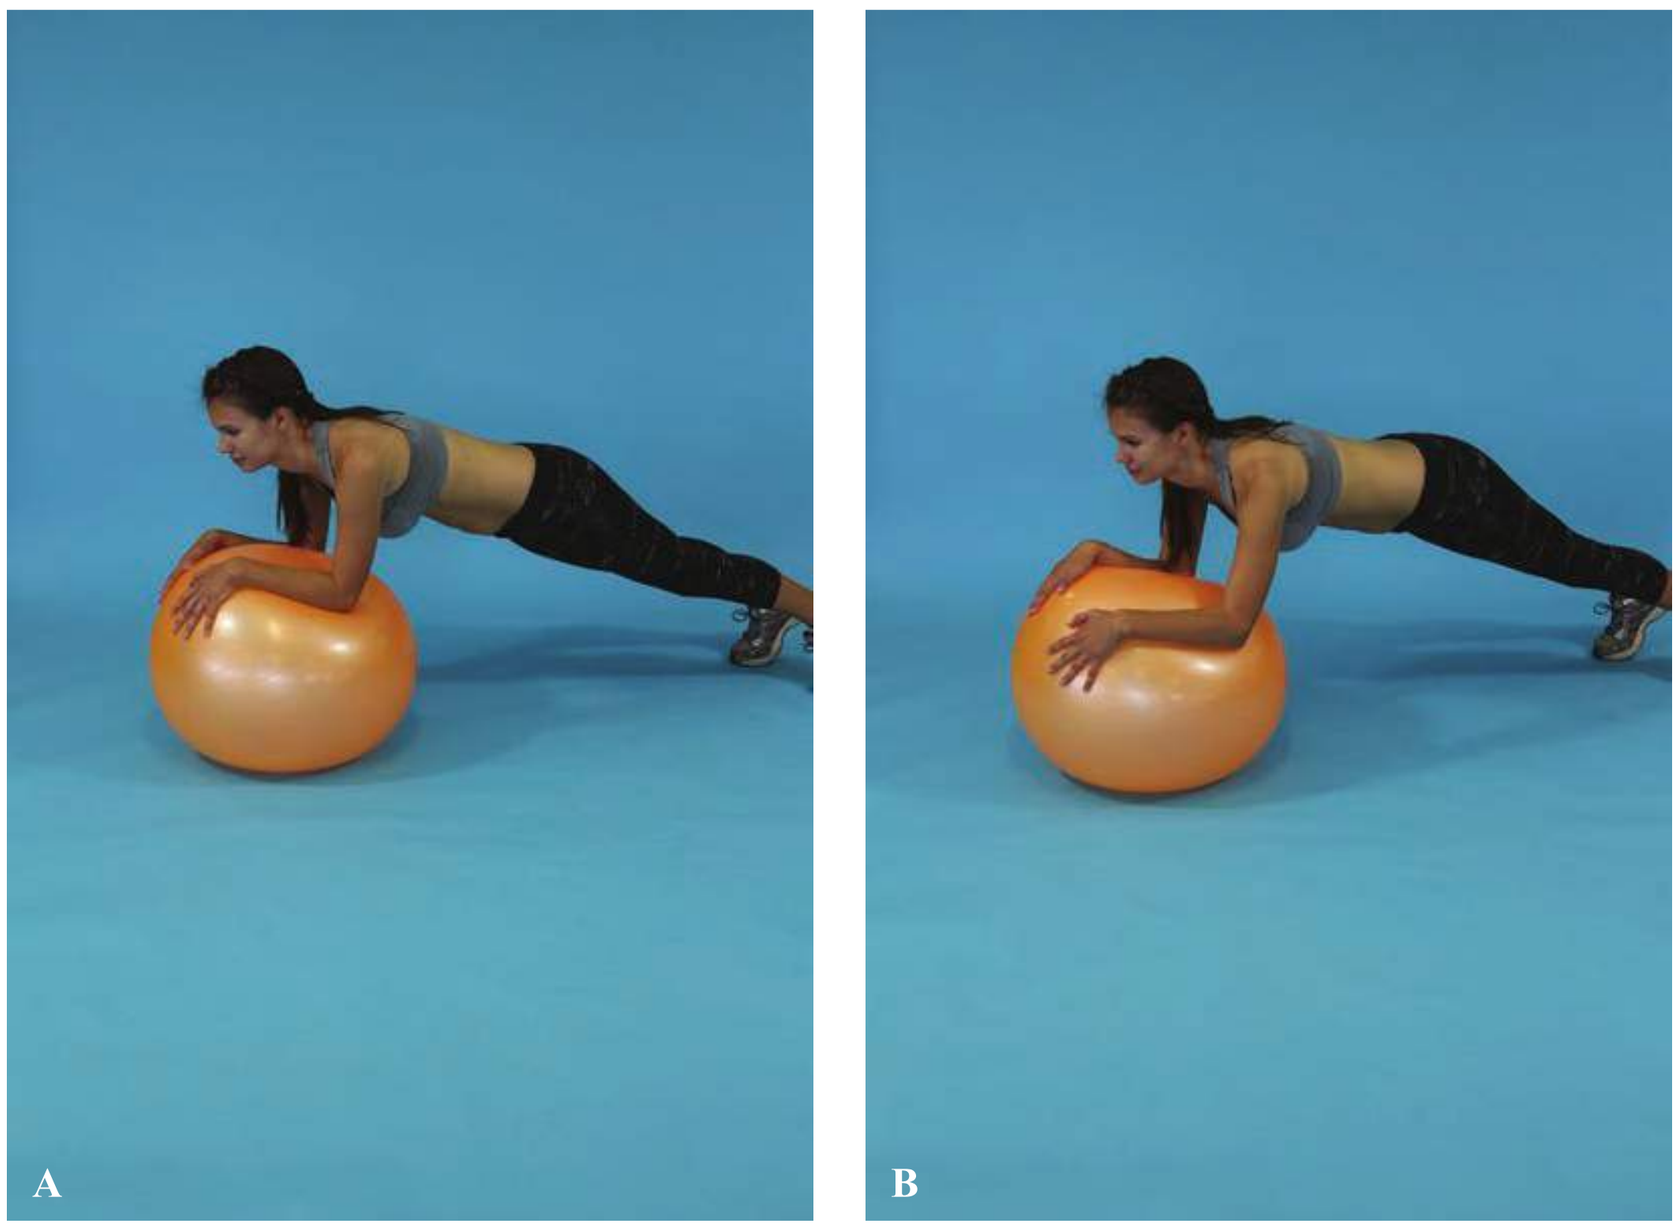

FIGURE 28-96 Stirring the pot.

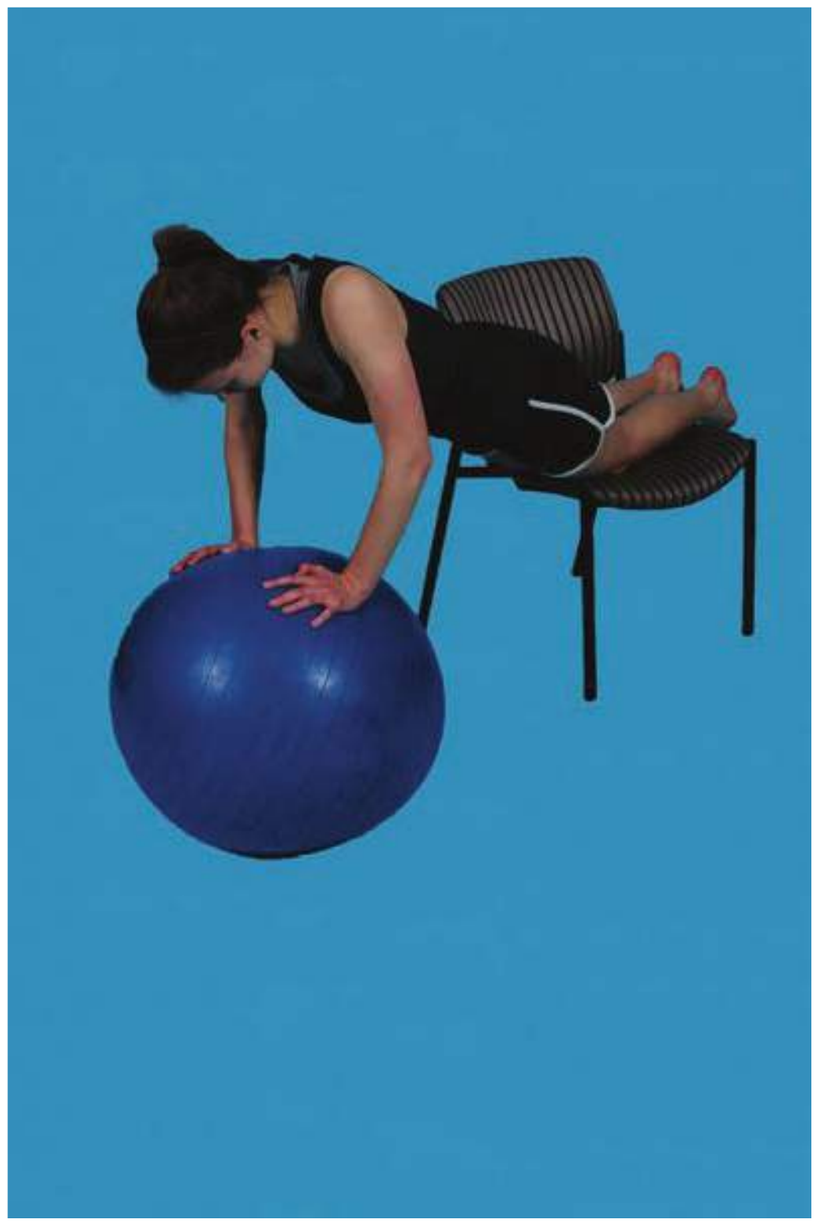

FIGURE 28-97 Push-ups with legs on a chair.

- Push-ups with legs on a chair (Fig. 28-97)
- Rhythmic stabilization. The patient is positioned in quadruped with one limb raised. The clinician applies perturbations to the patient while the patient attempts to resist using a variety of points of contact, and positions (Fig. 28-98). This exercise can be progressed by raising both an upper extremity and the contralateral lower extremity, positioning the patient on an unstable base, and by adding resistance.

Correction of Muscle Imbalances

In addition to addressing core stabilization, muscle imbalances must also be addressed in terms of flexibility as poor flexibility may cause excessive stresses to be borne by the lumbar motion segments. For example, adaptively shortened hip flexors and rectus femoris muscles can cause increased anterior shearing of the lumbar spine. Occasionally, stretching both the anterior and the posterior thigh muscles is beneficial. However, most of the time, only one should be stretched, and the decision is based on the diagnosis:

- The patient with spinal stenosis or a painful extension hypomobility, and who responds well to lumbar flexion exercises, should be taught how to stretch the hip flexors and rectus femoris while protecting the lumbar spine from excessive lordosis.
- The patient with a painful flexion hypomobility or IVD herniation, and who responds well to lumbar extension exercises, should be taught how to stretch the hamstrings while protecting the lumbar spine from flexing.

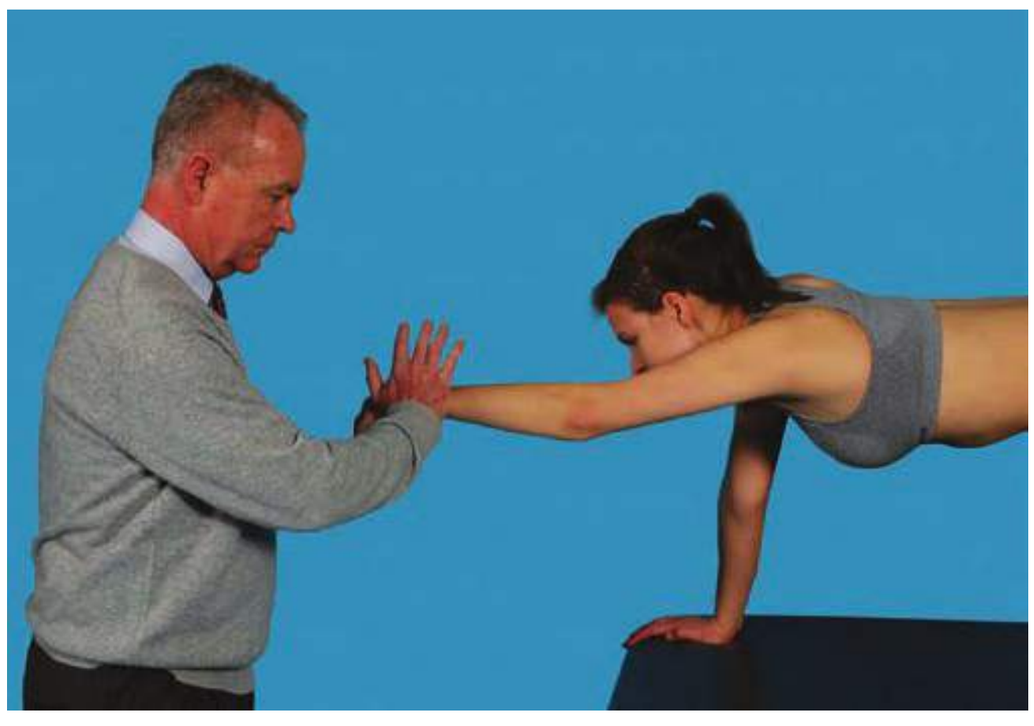

FIGURE 28-98 Rhythmic stabilization in quadruped.

Trunk Balance Exercises

A consistent finding in chronic LBP due to clinical instability is delayed activation of the trunk muscles during both unpredictable and predictable trunk perturbations.[678] As previously described, the trunk muscles that provide spinal stability act through feedforward and feedback control mechanisms that modulate the stiffness of the spinal muscles to control internal and external forces generated during body movements. The functional consequence of this delayed response is a deficit in trunk balance, possibly due to poor proprioception or position sense. This is manifested in patients with chronic LBP by a difficulty to maintain balance, especially under challenging conditions (e.g., single-limb support). Most of the rehabilitative protocols for improving trunk muscle activation primarily focus on the feedforward mechanism, with little emphasis on the feedback control mechanisms. The following balance exercises can be a useful adjunct when treating a patient with clinical instability:[678]

1. The patient kneels on a pillow with the arms abducted to 90 degrees (Fig. 28-99). The patient is asked to rotate the trunk, head, and upper limbs to the left so that the right arm is pointing forward before returning to the start position. The patient then turns in the opposite direction so that the left arm is pointing forward, and then returns to the start position. The exercise is repeated two times per direction maintaining each position for 30 seconds. The exercise is made more challenging by adding first eye closure, and then neck extension (Fig. 28-100).
2. The patient is positioned kneeling on a pillow with the arms out in front and hands clasped together (Fig. 28-101). The patient is asked to move the upper limbs into flexion and then extension with a simultaneous movement of the head. The position is maintained for 3 minutes, performing six repetitions of upper limbs movement. The exercise is made more challenging by adding neck extension and eye closure (Fig. 28-102).
3. The patient is positioned in supine in the hook lying position with the feet resting on the table. The patient is asked to lift the pelvis up (Fig. 28-103) and, after reaching maximum hip extension, to raise one lower limb from the table and extend the knee (Fig. 28-104). This is position is maintained twice for 30 seconds for each lower extremity. The exercises made more challenging by adding first eye closure and then a ball under the foot resting on the table

FIGURE 28-99 The patient kneels on a pillow with the arms abducted to 90 degrees.

FIGURE 28-101 Patient positioned kneeling on a pillow with the arms out in front and hands clasped together.

4. The patient is positioned in the quadruped position and is then asked to extend opposite upper and lower limbs (Fig. 28-105). The position is maintained for 1 minute for each combination of limbs. The exercise is made more challenging by first adding eye closure and then a pillow under the lower limb (Fig. 28-106).
5. The patient is positioned in sitting on the side of the table with unilateral support so that all of their weight is on

FIGURE 28-100 Eye closure and neck extension added.

FIGURE 28-102 Eye closure added.

FIGURE 28-103 Patient positioned in hook lying and lifts the pelvis.

one buttock (Fig. 28-107). T is position is maintained for 1 minute each side. T e exercise is made more challenging by adding eye closure, crossing the upper arms to the chest, neck extension, and putting a pillow under the lower limb (Fig. 28-108).

6. T e patient is positioned in single-limb kneeling on the edge of the table (Fig. 28-109). T e position is maintained for 30 seconds. Two repetitions are performed for each limb. T e exercise is made more challenging by first adding eye closure, then neck extension, a pillow, and finally arms across the chest (Fig. 28-110).

THERAPEUTIC TECHNIQUES

Manual therapy is a common intervention used in the treatment of individuals with LBP.

FIGURE 28-104 Patient raising one lower limb from the table and extending the knee.

FIGURE 28-105 Extending opposite upper and lower limbs in quadruped.

Techniques to Increase Joint Mobility

T ree types of techniques can be used to increase joint mobility. T ese include joint mobilizations, high-velocity thrust techniques, and muscle energy.

Joint Mobilizations and High-Velocity Thrust Techniques

T e Guide to Physical T erapist Practice identifies mobilization/manipulation as an intervention appropriate for the care of patients spinal disorders.[679] Several randomized trials have found manipulation to be more effective than placebo[680,681] or other interventions.[682,683] However other studies have not shown any benefits for manipulation versus other interventions.[505,684,685] T e literature tends to suggest that lumbar manipulation is most successful if performed in the subacute stage of a noncomplicated lumbar condition.[456,686] However,

FIGURE 28-106 Adding eye closure and a pillow under the lower limb.

FIGURE 28-107 Sitting on the side of the table with all of the weight through one buttock.

this description represents a very small percentage of patients with low-back dysfunction, and in most cases the patient is more likely to benefit from aerobic exercise, less invasive manual techniques, and dynamic stabilization training.[687]

Although a grade V technique shares similarities with a grade IV mobilization, in terms of amplitude and position in the joint's range, grade V differs in the velocity of delivery. Chapter 10 outlines the indications and contraindications for high-velocity thrust techniques. If a high-velocity thrust technique is to be used, the clinician should perform a pre-manipulative hold (see Chapter 10).

All of the examination techniques that are used to assess joint mobility can be employed as intervention techniques. However, the intent of the technique changes from one of assessing the end-feel to one in which the application of graded mobilizations, or muscle energy techniques, is applied at the appropriate joint range. T e selection of a manual technique is dependent on a number of factors, including (1) the acuteness of the condition, (2) the goal of the intervention, and (3) whether the restriction is symmetric or asymmetric.

CASE STUDIES

1. A 58-year-old woman presented with a gradual onset of low-back and sacroiliac joint pain. Her chief complaint was a "stiff" back, especially in the morning. The patient had experienced mild discomfort over several years but had noticed a recent increase in its intensity over the past few months. The pain was reported as being worse with prolonged standing, lifting, bending, and walking and was relieved by sitting and lying down. The pain occasionally was felt in the right buttock, hip, and thigh. A recent radiograph revealed the presence of "arthritic changes" in the lumbar spine.

   The patient reported being in good general health. There were no reports of night pain, bowel and bladder changes, or pain with coughing or sneezing.

   1. List the differential diagnosis for complaints of pain in the low back and sacroiliac joint.
   2. What may be the significance of a history of morning stiffness?
   3. List the potential reasons for the patient's symptoms being worsened with prolonged standing, lifting, bending, and walking and improved with sitting or lying?
   4. From the history, what are the indications that this may be a musculoskeletal problem?
   5. Which tests could you use to rule in/out the potential reasons for the patient's complaints?
   6. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

2. A 40-year-old man presented with a 3-month history of gradual onset of LBP, with no specific mechanism of injury. The pain was felt across the lower back at the level of the belt line. The patient reported no pain in the morning upon arising. The pain began soon after reporting to work as a cashier in a grocery store and worsened as the day wore on. The pain was also worsened with activities that involving prolonged walking or prone lying. The pain was relieved almost instantly by sitting or side lying, with the knees drawn to the chest. The patient had radiographs of the spine taken recently, which showed some evidence of arthritis but were otherwise unremarkable.

   The patient reported being in general good health. There were no reports of night pain, bowel and bladder changes, or pain with coughing or sneezing.

   1. List the differential diagnosis for complaints of a gradual onset of pain in the low back in this age group.
   2. What may be the significance of a history of no morning pain or stiffness?
   3. List the potential reasons for the patient's symptoms getting worse with prolonged standing, walking, and lying but better with sitting or the fetal position.
   4. From the history, what are the indications that LBP may be a musculoskeletal problem?
   5. What is your working hypothesis at this stage? Which tests could you use to confirm or refute your hypothesis?
   6. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

3. A 20-year-old man complained of a sudden onset of unilateral LBP. The pain was so severe as to prevent the patient from standing upright. The patient described a mechanism of bending forward quickly to catch a ball near his left foot. He immediately experienced a sharp pain in his low back and was unable to straighten up because of the pain. The patient had no past history of back pain. No spinal radiographs had been taken.[619]

   1. List the differential diagnosis for complaints of a gradual onset of unilateral LBP.
   2. What may be the significance of the reported mechanism?
   3. List the potential reasons for the patient being initially unable to straighten up from the flexed position.
   4. From the history, what are the indications that this may be a musculoskeletal problem?
   5. Would the results from imaging studies be useful in this case? Why or why not?
   6. What is your working hypothesis at this stage? Which tests could you use to confirm or refute your hypothesis?
   7. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

4. A 45-year-old woman was referred for LBP. She complained of pain across the center of her back at the waistline level. The pain, which had started gradually many years ago, had not spread from this small area, but it had increased in intensity. The increase in intensity resulted from a bending and lifting injury a few years previously, and, since that incident, the patient reported having dif culty straightening up from the bent-over position. Twisting maneuvers, whether in standing, sitting, or lying position, also produced the pain, but otherwise the woman was able to sit, stand, or walk for long periods without pain.

   1. List the differential diagnosis for complaints of a gradual onset of central LBP.

2. What may be the significance of the insidious onset?
3. List the potential reasons for the patient having difficulty straightening up from the flexed position.
4. From the history, what are the indications that this may be a mechanical problem?
5. Would the results from imaging studies be useful in this case? If so, which?
6. What is your working hypothesis at this stage? Which tests could you use to confirm or refute your hypothesis?
7. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

5. A 65-year-old man presented with an insidious onset of right leg symptoms, which followed a period, or distance, of walking, or occurred after a period of standing, and which disappeared when he sat down. The patient also complained of pain at night, especially when he slept on his stomach. Further questioning revealed that the patient had a history of back pain related to an occupation involving heavy lifting but was otherwise in good health and had no reports of bowel or bladder impairment.
   1. Given the age of the patient and the history, do you have a working hypothesis?
   2. Why do you think the patient has pain with prone lying?
   3. Is the pain at night a cause for concern in this patient? Why?
   4. Does this presentation/history warrant a scanning examination? Why or why not?

6. A 21-year-old woman presented with LBP that had occurred while playing racket ball and had been accompanied by a sharp pain in the right buttock area. The patient was able to carry on playing, and the sharp pain subsided until the following morning, when attempted to weight bear through the right leg. The pain again subsided after a hot shower and her walk to work. That evening, the patient went jogging and was forced to stop after about a mile because of the return of the sharp pain in the buttock. A hot soak eased the pain but was replaced by a dull ache that lasted several days. The patient sought medical advice and was referred to physical therapy. When asked to indicate where her pain was, she pointed to a small area, medial to the right trochanter, over the piriformis muscle. Further questioning revealed that the patient had no previous history of back pain and was otherwise in good health, with no reports of bowel or bladder impairment.
   1. What structure(s) could be at fault with complaints of buttock pain?
   2. What does the history of the pain tell the clinician?
   3. What is your working hypothesis at this stage? List the various diagnoses that could present with buttock pain, and the tests you would use to rule out each one.
   4. Does this presentation/history warrant a scan? Why or why not?

CHAPTER 29 The Sacroiliac Joint

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the bones, the ligaments, the muscles, and the blood and nerve supply that comprises the sacroiliac (SI) region.
2. Describe the biomechanics of the sacroiliac joint (SIJ), including coupled movements, normal and abnormal joint barriers, kinesiology, and reactions to various stresses.
3. Perform a detailed objective examination of the SIJ, including palpation of the articular and the soft-tissue structures, specific passive mobility tests, passive articular mobility tests, and stability tests.
4. Evaluate the total examination data to establish the diagnosis.
5. Describe the intervention strategies based on clinical findings and established goals.
6. Design an intervention based on patient education, manual therapy, and therapeutic exercise.
7. Apply active and passive mobilization techniques, and combined movements to the SIJ, in any position using the correct grade, direction, and duration.
8. Describe the common pathologies and lesions of this region.
9. Evaluate intervention effectiveness in order to progress or modify an intervention.
10. Plan an effective home program and instruct the patient in this program.

OVERVIEW

T e sacroiliac joint (SIJ) serves as the supporting base of the spine and as the point of intersection between the spinal and the lower extremity joints. T e SIJ is the least understood and, therefore, one of the most controversial and interesting areas of the spine. Determining a diagnosis in this region is complicated by the biomechanics of the SIJ and its relationships with the surrounding joints, including the hip, pubic symphysis, and lumbar spine.

Grieve[1] has proposed that the SIJ, together with the other areas of the spine that serve as transitional areas, is of prime importance in understanding vertebral joint problems. T is level of importance is perhaps surprising because isolated pelvic impairments are rare. However, findings for SIJ dysfunction appear to be common, and the literature is replete with intervention techniques aimed at correcting pelvic dysfunctions.[2–11] T is may be explained by the fact that, in addition to being able to produce pain on its own, the SIJ often can refer pain.[12]

T e level of interest surrounding this joint dates back to the Middle Ages, a time when the burning of witches was commonplace. It was noticed after these burnings that three of the bones were not destroyed: a large triangular bone and two very small bones. It can only be assumed that some degree of significance was given to the large triangular bone as it was deemed a sacred bone and was thus called the sacrum. It is unclear what significance was given to the two smaller bones, the sesamoid bones of the great toe.

Despite these illustrious beginnings for the sacrum, it was not until approximately 100 years ago that significant attention was applied to the study of pelvic anatomy and function, and its relationship to low back and pelvic pain. At the start of the 20th century, SIJ strain was thought to be the most common cause of sciatica.[13] T en, in 1934, Mixter and Barr[14] reported that sciatica could be caused by a prolapsed intervertebral disk, and the interest in the SIJ as a source of sciatica dwindled. Since then, there have been periods when the joint has been blamed for almost all low back and leg pain, and times when it has only been considered a problem during pregnancy. It is now generally accepted that approximately 13% (95% CI: 9–26%) of patients with persistent low back pain have the origin of pain confirmed as the SIJ.[15]

ANATOMY

Anatomically, the SIJ is a large diarthrodial joint that connects the spine with the pelvis (Fig. 29-1) and which serves as a central base through which forces are transmitted both

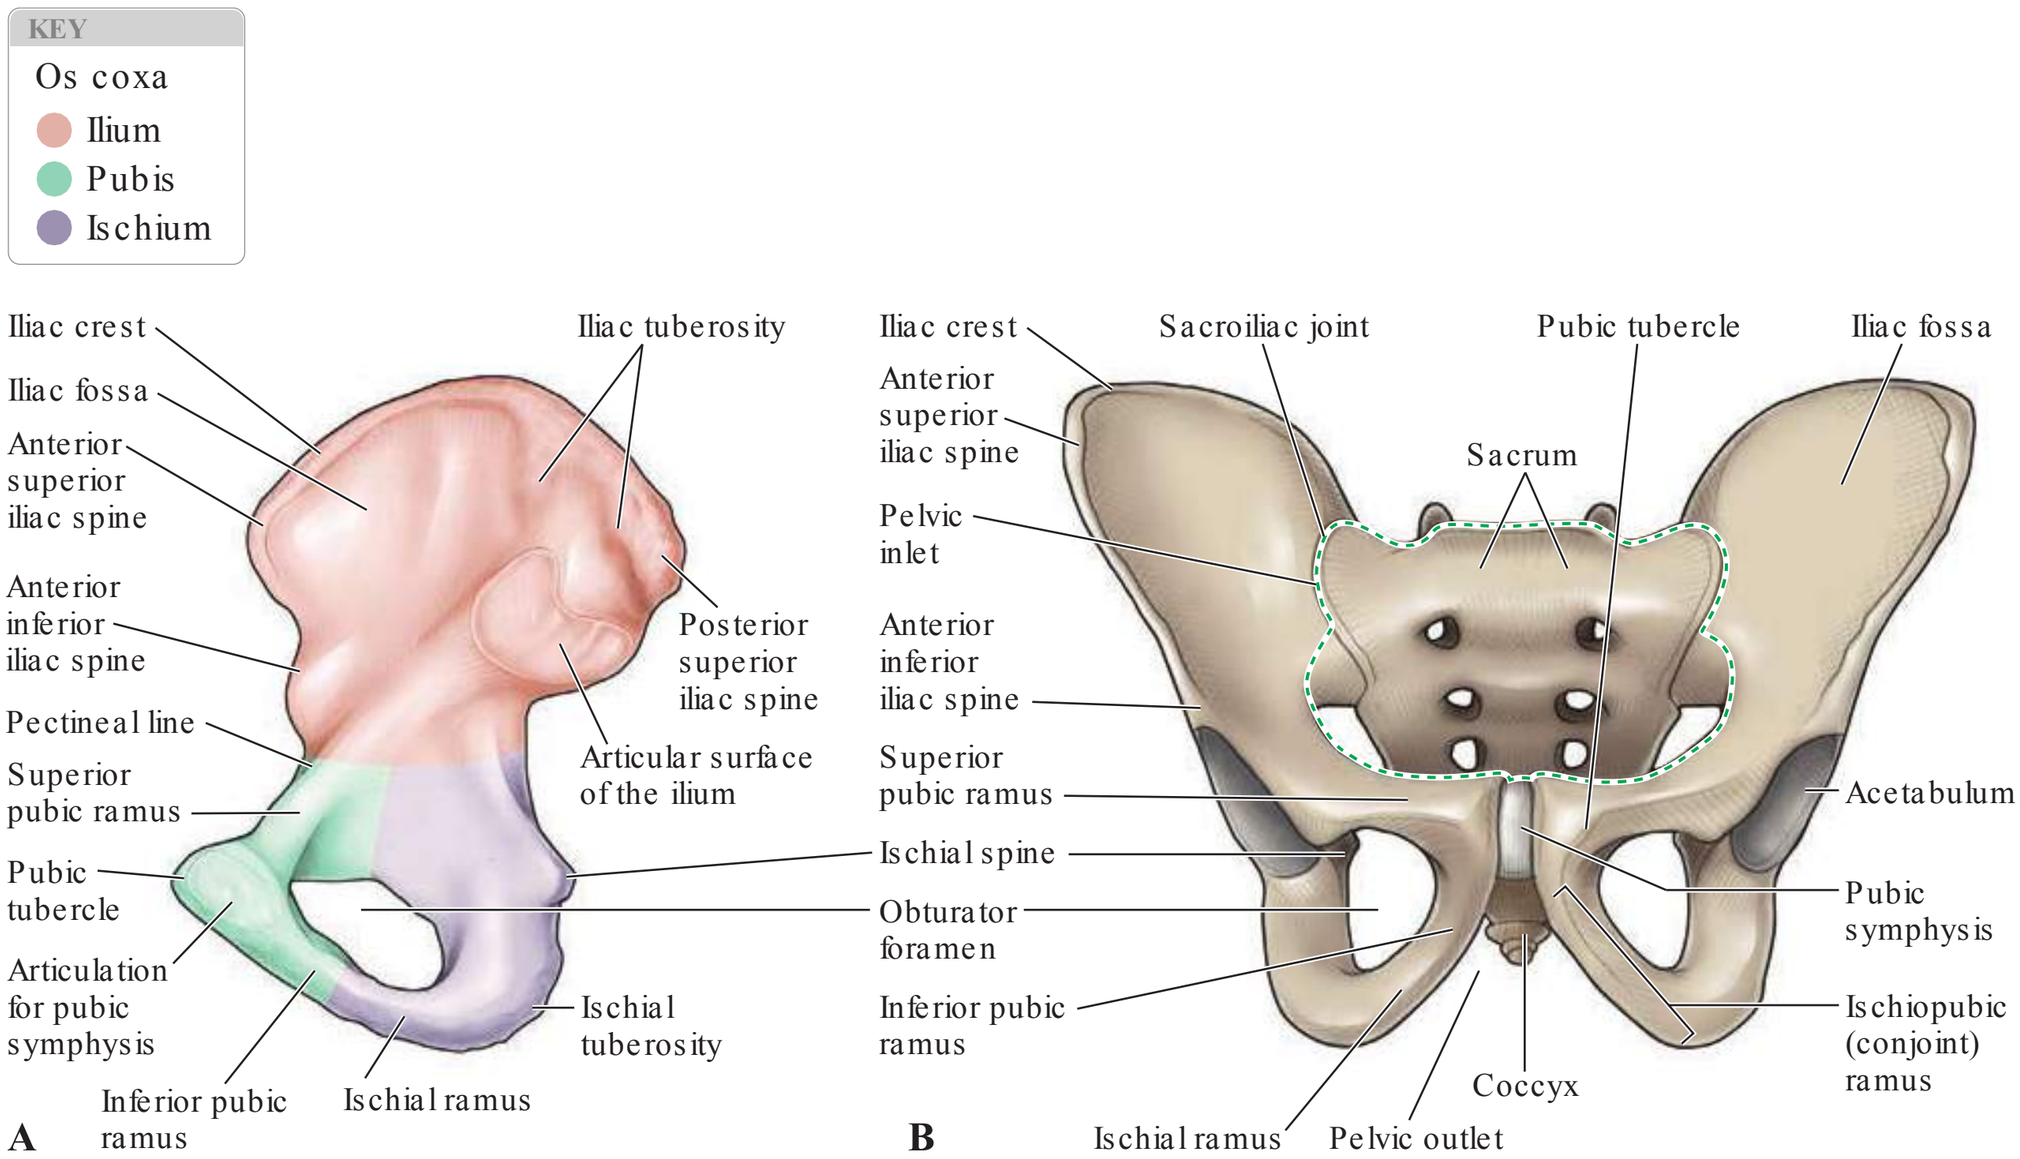

FIGURE 29-1 The pelvis. (Reproduced, with permission, from Chapter 6. Headache & Facial Pain. In: Greenberg DA, Aminoff MJ, Simon RP. eds. Clinical Neurology, 8e. New York, NY: McGraw-Hill; 2012.)

directly and indirectly. The structure of the pelvis and its surrounding tissues has evolved in conjunction with the evolutionary changes in human gait. Three bones comprise the SIJ: two innominates and the sacrum.

Sacrum

The sacrum (Fig. 29-1), a strong and triangular bone located between the two innominates, provides stability to this area and transmits the weight of the body from the mobile vertebral column to the pelvic region. Evolutionary changes have resulted in an increased size of the sacrum to accommodate the increased osseous attachment of the gluteus maximus muscle, and to facilitate the increased compression produced in a bipedal stance.[11] The sacrum base is above and anterior, and its apex below and posterior (Fig. 29-1). This is differs from nonhuman mammals in which the sacral base is horizontal, and the lumbar spine is kyphotic.[11] Five centra fuse to form the central part of the sacrum, which contains remnants of the intervertebral disks enclosed by bone. The sacrum has four pairs of pelvic sacral foramina for transmission of the anterior (ventral) primary rami of the sacral nerves and four pairs of posterior (dorsal) sacral foramina for transmission of the posterior (dorsal) primary rami.

The transverse processes of the first sacral vertebra fuse with the costal elements to form the ala and the lateral crests (see Fig. 29-1). The ala of the sacrum forms the superolateral portions of the base. The superior articular processes of the sacrum (Fig. 29-1), which are concave and oriented posteromedially, extend upward from the base to articulate with the inferior articular processes of the fifth lumbar vertebra.

On the posterior (dorsal) surface of the sacrum is a midline ridge of bone called the median sacral crest, which represents the fusion of the sacral spinous processes of S1 to S4. Projecting posteriorly from this crest are four spinous tubercles. The fused laminae of S1 to S5, which are located lateral to the median sacral crest, form the intermediate sacral crest.

The sacral hiatus exhibits bilateral downward projections that are called the sacral cornua. These projections represent the inferior articular processes of the fifth sacral vertebra and are connected to the coccyx via the intercornual ligaments. On the inferolateral borders of the sacrum, approximately 2 cm to either side of the sacral hiatus, are the inferior lateral angles (ILAs). The triangular sacral canal houses the cauda equina. In addition to the more commonly considered bones and joints are those of the coccygeal spine. The coccyx, which is variable in size, consists of three to five vertebral units that are usually fused, with the exception of the first segment, which articulates with the distal end of the sacrum, and is referred to as the sacrococcygeal joint.[16] In general, the posterior (dorsal) surface of the coccyx is convex, so that its inferior aspect slopes anteriorly.

Innominates

The ilium, ischium, and pubic bone fuse at the acetabulum to form each innominate (Fig. 29-1). The ilium of each of the two innominates articulate with the sacrum, forming the SIJ, and the pubic bone of each of the innominates articulate with each other at the symphysis pubis. The ilia have undergone significant adaptations in response to bipedalism in such a way that the bone has twisted so that the lateral aspect is now directed anteriorly, and the gluteus medius and minimus muscles have migrated anteriorly with a resultant change in their function.[11]

Sacroiliac Joint

The articulating surfaces of this joint differ, with the joint surface of the ilium formed from fibrocartilage and the sacral surface formed from hyaline cartilage.[17] The SIJ is in part synovial (25% of its surface) and in part syndesmosis, and so between the sacral and iliac auricular surfaces, the SIJ is deemed a synovial articulation or diarthrosis.[18,19]

The inverted, L-shaped, auricular articular surface of the sacrum (Fig. 29-1) is surrounded entirely by the costal elements of the first three sacral segments. The short (superior) arm of this L-shape lies in a craniocaudal plane, within the first sacral segment, and corresponds to the depth of the sacrum (see Fig. 29-1). It is widest superiorly and anteriorly. The long (inferior) arm of the L-shape lies in an anteroposterior (A-P) plane, within the second and third sacral segments, and represents the length of the sacrum from top to bottom. It is widest inferiorly and posteriorly. There are large irregularities on each articular surface[20] that are approximately, though not exactly, reciprocal, with the sacral contours being generally deeper.[21,22] In addition to the larger irregularities, there are smaller horizontal crests and hollows that run anteroposteriorly. The sacral articular surface is wedge shaped in its upper portion, formed by the first sacral segment and half of the second. Below this, the joint surfaces run nearly vertically and then diverge somewhat, making a flare which tends to prevent the sacrum from sliding upward between ilia.[22]

The morphology varies in size, shape, and contour from side to side, and between individuals and changes with aging.[23] In fact, variations in the SIJ morphology are so common that they have been classified as type A, being less vertical than type B, and type C as an asymmetric mixture of types A and B.[5] Each of these variants can alter the function of the pelvis and its influence on the lumbar lordosis.[24]

CLINICAL PEARL

The configuration of the SIJ is extremely variable from person to person and between genders in terms of morphology and mobility.[22,25,26] However, it has been determined that these differences are not pathological, but normal adaptations.[25]

The articulating surfaces of the joint respond differently to the aging process, with early degenerative changes occurring on the iliac surface rather than on both surfaces of the joint simultaneously.[27] Other changes associated with aging include the development of intraarticular fibrous connections.[28] However, even with severe degenerative changes, the SIJ rarely fuses.[18]

The SIJ can be the site of manifestation for several disease processes, including SI tuberculosis, spondyloarthropathy (ankylosing spondylitis), and crystal and pyogenic arthropathies.

Joint Capsule

The SIJ capsule, consisting of two layers, is extensive and very strong. It attaches to both articular margins of the joint and is thickened inferiorly.

Ligaments

Like other synovial joints, the SIJ is reinforced by ligaments, but the ligaments of the SIJ are some of the strongest and toughest ligaments of the body.

Anterior Sacroiliac (Articular)

The anterior sacral ligament (Fig. 29-2) is an anteroinferior thickening of the fibrous capsule, which is relatively weak and

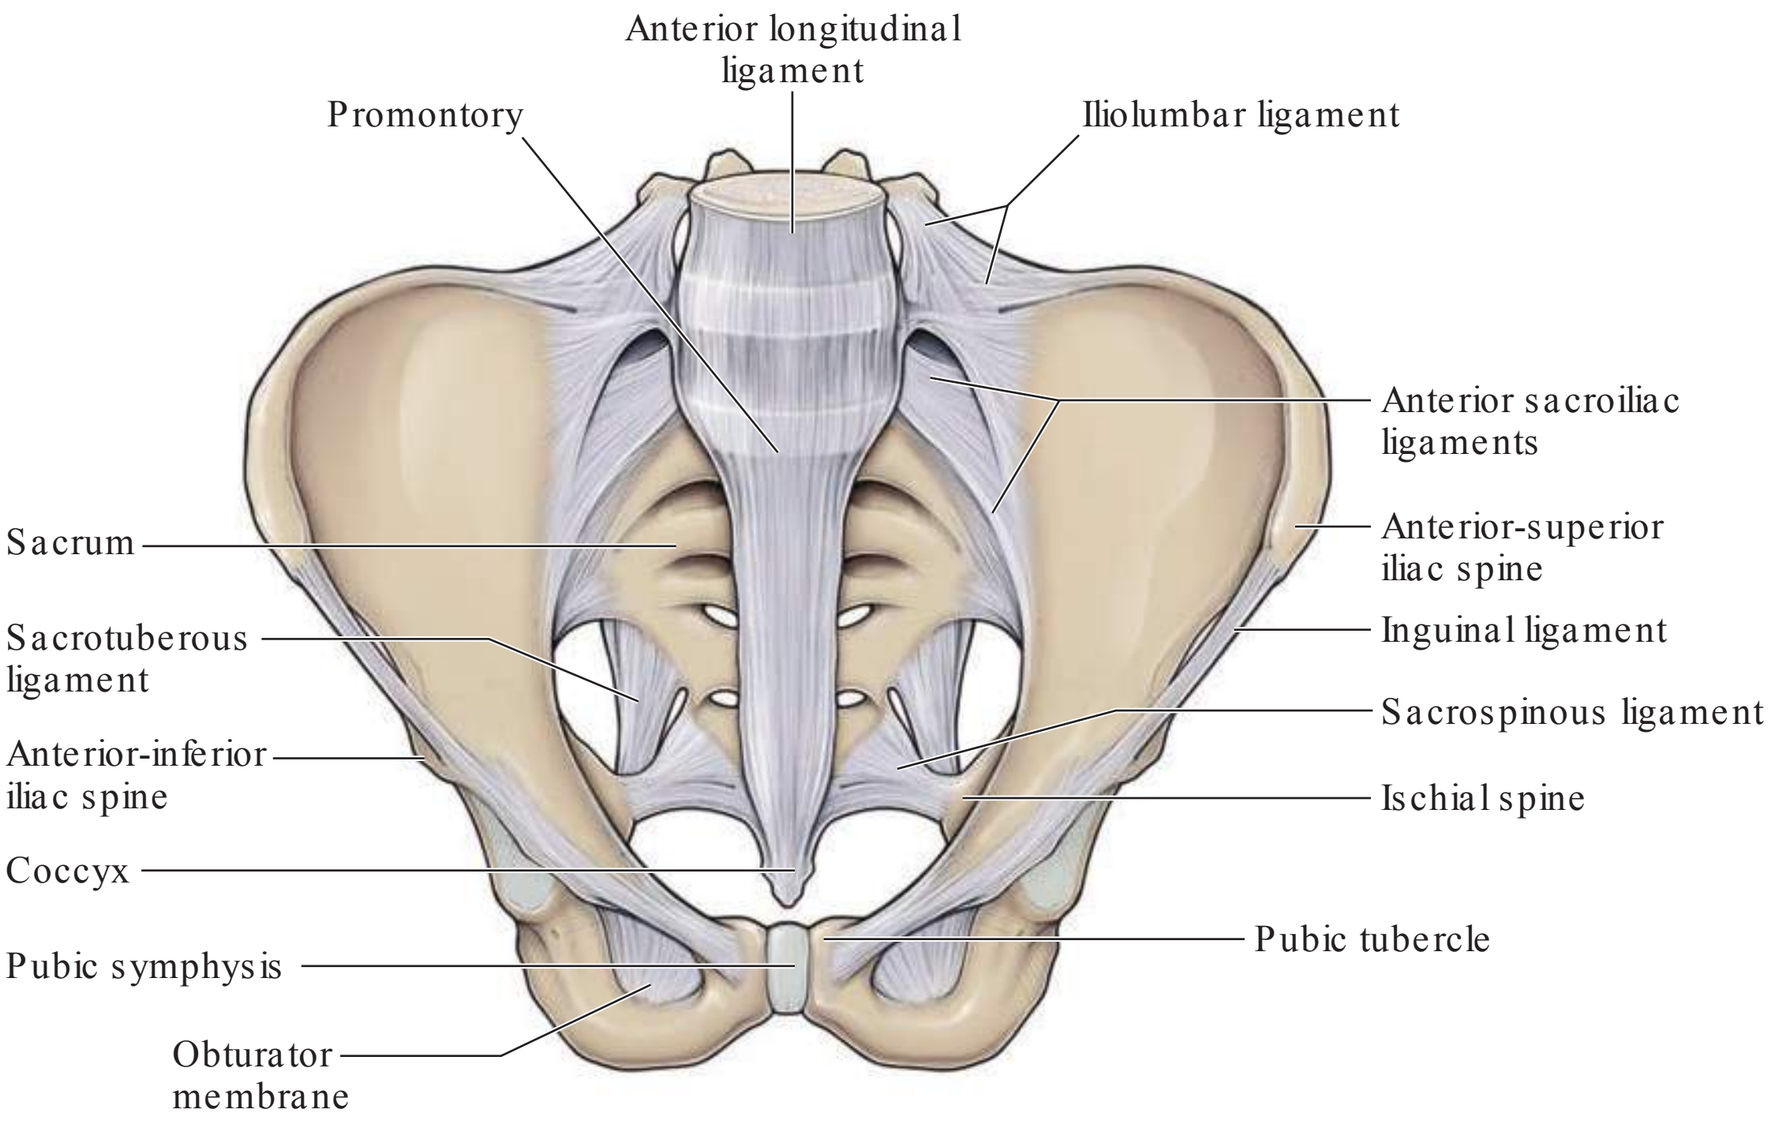

FIGURE 29-2 Anterior ligaments.

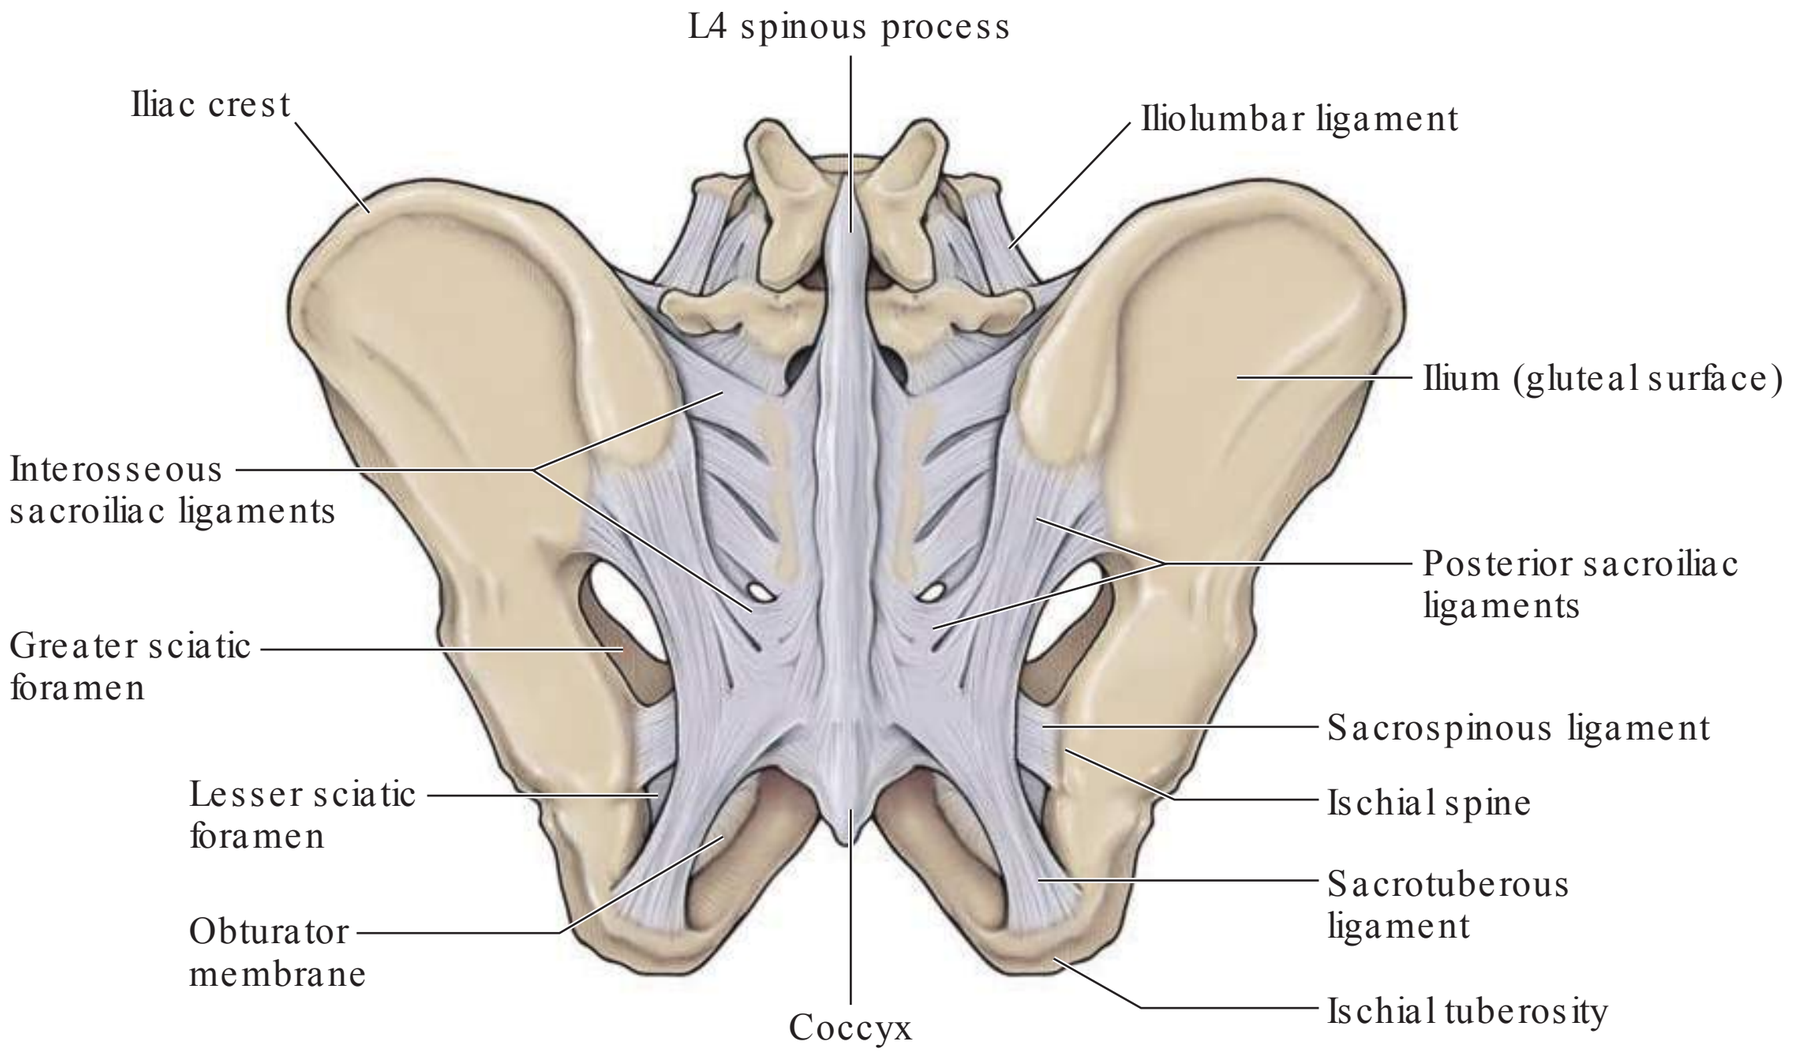

FIGURE 29-3 Posterior ligaments.

thin compared to the rest of the SI ligaments. The ligament extends between the anterior and inferior borders of the iliac auricular surface and the anterior border of the sacral auricular surface.[18] The anterior sacral ligament is better developed near the arcuate line and the posterior-inferior iliac spine (PIIS), where it connects the third sacral segment to the lateral side of the preauricular sulcus.

Because of its thinness, this ligament is often injured and can be a source of pain. It can be palpated at Baer's SI point*[29] and can be stressed using the anterior distraction and posterior compression pain provocation tests (see later).

Interosseous Sacroiliac (Articular)

This is a strong, short ligament located deep to the posterior (dorsal) SI ligament, and it forms the major connection between the sacrum and the innominate, filling the irregular space posterosuperior to the joint between the lateral sacral crest and the iliac tuberosity (Fig. 29-3).[30] The deep portion sends fibers cranially and caudally from behind the auricular depressions. The superficial portion is a fibrous sheet connecting the superior (cranial) and posterior (dorsal) margins of the sacrum to the ilium, forming a layer that limits direct palpation of the SIJ. The interosseous SI ligament functions to resist anterior and inferior movement of the sacrum.

Posterior (Dorsal) Sacroiliac (Articular)

The posterior (dorsal) SI ligament or long ligament (see Fig. 29-3), which is easily palpable in the area directly caudal to the posterior-superior iliac spine (PSIS), connects the PSIS (and a small part of the iliac crest) with the lateral crest of the third and fourth segments of the sacrum.[31] This is a very tough and strong ligament. The fibers of this ligament are multidirectional and blend laterally with the sacrotuberous ligament. It also has attachments medially to the erector spinae[32] and multifidus muscles[33] and the thoracodorsal fascia. Thus, contractions of the various muscles that attach to this ligament can result in the tightening of the ligament.

Directly caudal to the PSIS, the ligament is so solid and stout that one can easily think a bony structure is being palpated. What complicates matters is the fact that the area overlying the ligament is a frequent source of pain.[34]

The lateral expansion of the long ligament in the region directly caudal to the PSIS varies between 15 and 30 mm. The length, measured between the PSIS and the third and fourth sacral segments, varies between 42 and 75 mm. The lateral part of the posterior (dorsal) ligament is continuous with fibers passing between ischial tuberosity and iliac bone.

At the superior (cranial) aspect, the posterior (dorsal) ligament is attached to the PSIS and the adjacent part of the ilium, at the inferior (caudal) side to the lateral crest of the third and fourth, and occasionally to the fifth, sacral segments.[32]

Nutation (anterior motion) of the sacrum appears to slacken the posterior (dorsal) ligament, whereas counternutation (posterior motion) tautens the ligament.[32]

Sacrotuberous (Extraarticular)

This ligament (see Fig. 29-3) is composed of three large fibrous bands, broadly attached by its base to the PSIS, the lateral sacrum, and partly blended with the posterior (dorsal) SI ligament. Its oblique, lateral fibers descend and attach to the medial margin of the ischial tuberosity, spanning the piriformis muscle from which it receives some fibers. The medial fibers, running anteroinferior and laterally, have an attachment to the transverse tubercles of S3, S4, and S5, and the lateral margin of the coccyx. To the posterior surface of the sacrotuberous ligament are attached the lowest fibers of

*Baer's SI point has been described as being on a line from the umbilicus to the ASIS, 5 cm from the umbilicus.

the gluteus maximus and the piriformis, the contraction of which produces increased tension in the ligament.[35] Superficial fibers on the inferior aspect of the ligament can continue into the tendon of the biceps femoris.

In addition to stabilizing against nutation of the sacrum, the sacrotuberous ligament also counteracts against the posterior (dorsal) and superior (cranial) migration of the sacral apex during weight bearing.[36,37]

Sacrospinous (Extraarticular)

T inner than the sacrotuberous ligament, this triangular-shaped ligament extends from the ischial spine to the lateral margins of the sacrum and coccyx, and also laterally to the spine of the ischium (see Fig. 29-3). T e ligament runs anterior (deep) to the sacrotuberous ligament to which it blends and then attaches to the capsule of the SIJ.[33]

T e sacrotuberous and sacrospinous ligaments, which convert the greater and lesser sciatic notches into the greater and lesser foramen respectively, oppose forward tilting of the sacrum on the innominates during weight bearing of the vertebral column.

Iliolumbar (Indirect)

T e anatomy of the iliolumbar ligament (Fig. 29-2) is described in Chapter 28.

Pubic Symphysis

T e pubic symphysis is classified as a symphysis because it has no synovial tissue or fluid, and it contains a fibrocartilaginous lamina or disk (Fig. 29-2). T e bone surfaces of the joint are covered with hyaline cartilage but are kept apart by the presence of the disk.

T e following are the supporting ligaments of this joint[21]:

- Superior pubic ligament, a thick fibrous band.
- Inferior arcuate pubic ligament, which attaches to the inferior pubic rami bilaterally and blends with the articular disk.
- Posterior pubic ligament, a membranous structure that blends with the adjacent periosteum.
- Anterior ligament, a very thick band that contains both transverse and oblique fibers.

T e pubic symphysis is a common source of groin pain, particularly in athletes (see section "Groin Pain").

Muscles

Lee[11] lists 35 muscles that attach directly to the sacrum or innominate, or both (Table 29-1). A muscle attaching to bone has the potential for moving that bone, although the degree of potential varies. Rather than producing movement at the SIJ, the muscles around the pelvis are more likely involved directly or indirectly in helping to provide stability to the joint.

Piriformis

T is muscle (see Chapter 19) arises from the anterior aspect of the S2, S3, and S4 segments of the sacrum; the capsule of the SIJ; and the sacrotuberous ligament. It exits from the pelvis via the greater sciatic foramen, before attaching to the upper border of the greater trochanter of the femur.

T e piriformis primarily functions to produce external rotation and abduction of the femur, but is also thought to function as an internal rotator and abductor of the hip if the hip joint is flexed beyond 90 degrees. It also helps to stabilize the SIJ, although too much tension from it can restrict the motion of this joint.[38] T e piriformis has been implicated as the source for a number of conditions in this area, including the following two

- Entrapment neuropathies of the sciatic nerve (piriformis syndrome.[39–45]). Piriformis syndrome is described in Chapter 5.
- Trigger and tender points.

TABLE 29-1 Muscles That Attach to the Sacrum, Ilium, or Both

Psoas minor
Adductor brevis
Adductor longus
Levator ani
Sphincter urethrae
Superficial transverse perineal ischiocavernosus
Coccygeus

Transversus Abdominis

The transversus abdominis (TrA) is the deepest abdominal muscle and arises from the lateral one-third of the inguinal ligament, the anterior two-thirds of the inner lip of the iliac crest, the lateral raphe of the thoracolumbar fascia, and the inner surface of the lower six costal cartilages, interdigitating with the costal fibers of the diaphragm.[11] For a detailed description of the anatomy and function of the TrA, refer to Chapter 28. Although the TrA does not cross the SIJ directly, it can affect the stiffness of the pelvis through its direct anterior attachments to the ilium, as well as its attachments to the middle layer and the deep laminae of the posterior layer of the thoracodorsal fascia.[46,47]

Multifidus

The anatomy of the multifidus muscle is described in Chapter 28. Some of the deepest fibers of the multifidus attach to the capsules of the zygapophyseal joints[48] and are located close to the centers of rotation of spinal motion. They connect adjacent vertebrae at appropriate angles, and their geometry remains relatively constant through a range of postures, thereby enhancing spinal stability.[49]

Erector Spinae

For a detailed description of the anatomy of the erector spinae, refer to Chapter 28. Through its extending effect on the spine and its substantial sacral attachments, the erector spinae might be thought to promote sacral nutation, although this has not been proven.

Gluteus Maximus

This is one of the strongest muscles in the body (see Chapter 19). It arises from the posterior gluteal line of the innominate, the posterior aspect of the lower lateral sacrum and coccyx, the aponeurosis of erector spinae muscle, the superficial laminae of the posterior thoracodorsal fascia, and the fascia covering the gluteus medius muscle, before attaching to the gluteal tuberosity. In the pelvis, the gluteus maximus blends with the ipsilateral multifidus, through the raphe of the thoracodorsal fascia,[33] and the contralateral latissimus dorsi, through the superficial laminae of the thoracodorsal fascia.[50] Some of its fibers attach to the sacrotuberous ligament. Tension in the sacrotuberous ligament increases when these fibers contract.[51]

Iliacus

This muscle arises from the iliac fossa (see Chapter 19), the iliac crest, the anterior SI ligament, the inferior fibers of the iliolumbar ligament,[52] and the lateral aspect of the sacrum. As it travels distally, its fibers merge with the lateral aspect of the psoas major tendon to form the iliopsoas, which continues onto the lesser trochanter of the femur, sending some fibers to the hip joint capsule as it passes.

Long Head of the Biceps Femoris

The long head of the biceps femoris originates from the ischial tuberosity and sacrotuberous ligament. In addition to functioning as a hip extensor and knee flexor (see Chapter 19, the long head of the biceps femoris, due to its connections to the sacrotuberous ligament, may also have a proprioceptive role during activities such as gait.

Pelvic Floor Musculature

The term "pelvic floor muscles" primarily refers to the levator ani, a muscle group composed of the pubococcygeus, puborectalis, and iliococcygeus. The levator ani muscles join the coccygeus muscles to complete the pelvic floor. The pelvic floor muscles work in a coordinated manner to increase intraabdominal pressure, provide rectal support during defecation, inhibit bladder activity, help support the pelvic organs, and assist in lumbopelvic stability.[53]

Levator Ani. The levator ani (Fig. 29-4) originates anteriorly from the pelvic surface of the pubis, posteriorly from the inner surface of the ischial spine, and from the obturator fascia. It inserts into the front and sides of the coccyx, to the sides of the rectum, and into the perineal body. The levator ani forms the floor of the pelvic cavity, functions to constrict the lower end of the rectum and vagina, and can also be activated during forced expiration.

The muscle, which consists of anterior, intermediate, and posterior fibers, is innervated by the muscular branches of the pudendal plexus.

Anterior Fibers. The anterior fibers insert into the perineal body, comprise the levator prostatae or sphincter vaginae, and form a sling around the prostate or vagina.

Intermediate Fibers

- Puborectalis. The puborectalis (see Fig. 29-4) originates at the pubis and forms a sling around the junction of the rectum and the anal canal. The muscle pulls the anorectal junction anteriorly, assisting the external sphincter in anal closure.
- Pubococcygeus. The pubococcygeal muscle (see Fig. 29-4) arises from the pubis and its superior ramus and passes posteriorly to insert into the anococcygeal body between the coccyx and the anal canal. The muscle functions to pull the coccyx forward. It also serves to elevate the pelvic organs and compress the rectum and vagina.
- Posterior Fibers. The iliococcygeal muscle (see Fig. 29-4) arises from the arcus tendineus and ischial spine and inserts onto the last segment of the coccyx and the anococcygeal body. The muscle functions to pull the coccyx from side to side and to elevate the rectum.
- Levator Plate. The pubococcygeal muscle and the iliococcygeal muscle unite posterior to the anorectal junction to form the levator plate, which inserts into the coccyx.
- Coccygeus. This muscle (Fig. 29-4) arises from the pelvic surface of the ischial spine and sacrospinous ligament and inserts on the coccyx margin and side of the lowest segment of the sacrum. Supplied by the muscular branches of the pudendal plexus, the coccygeus functions to pull forward and support the coccyx. In addition, the coccygeus muscle provides support for the pelvic contents and the SIJ.

Neurology

It remains unclear precisely how the anterior and posterior aspects of the SIJ in humans are innervated, although the anterior portion of the joint likely receives innervation from the posterior rami of the L2 to S2 roots.[54] Contribution from these root levels is highly variable and may differ among the joints of given individuals.[55] Additional innervation to the anterior joint may arise directly from the obturator nerve, superior gluteal nerve, or lumbosacral trunk.[22,56] The posterior portion of the joint is likely innervated by the posterior rami of L3 to S3, with a particular contribution from S1 and S2.[57] An additional autonomic component of the joint's innervation further increases the complexity of its neural supply

and likely adds to the variability of pain referral patterns from this area.[56,58]

The current reference standard for confirming pain stemming from the SIJ is fluoroscopically guided, contrast-enhanced, intraarticular anesthetic blocks.[59] Using this method, the SIJ has been identified in 10% to 27% of patients with low back pain as a source of their primary pain.[15,60,61] Mechanical pain resulting from SIJ dysfunction may manifest as sacral pain but may also refer pain distally. For example, SIJ problems can refer pain to the iliac fossa, the buttock, the groin, the superior lateral and posterior thigh, and rarely below the knee.[62] In general, SIJ pain is characterized by unilateral pain below the level of L5, in the absence of midline pain, whereas irritation of a spinal nerve may cause radicular symptoms below the knee.[63] Pubic symphysis dysfunction typically results in localized pain, or groin pain, which is aggravated by activities involving the hip adductor or rectus abdominis muscles.[64] However, studies have shown that using evidence of pain referral patterns, or evidence of groin pain is neither sensitive nor specific for SIJ dysfunction.[65]

Pain also may be referred to the sacrum from a distant structure, including the contralateral sacrospinalis muscle,[66] the ipsilateral interspinous ligaments of L3 to S2,[67] and the L4 to L5 facet joints.[68] In addition, it is well established that dysfunctional pelvic floor muscles can contribute to the symptoms of interstitial cystitis and the so-called urethral syndrome, which is urgency frequency with or without chronic pelvic pain.[69–71]

BIOMECHANICS

Motions at the neighboring lumbar spine predominantly occur around the sagittal plane and comprise flexion and extension, whereas the motions occurring at the hip occur in three planes and include the one motion that the lumbar spine does not tolerate well, that is, rotation. Thus, the pelvic area must function to transfer the loads generated by body weight and gravity during standing, walking, sitting, and other functional tasks.[72] To date, there is very little agreement, either among or even within disciplines, about how the structures of the pelvis achieve this. For many decades, it was thought that the SIJ was immobile due to the close fitting nature of the articular surfaces. Research has now shown that mobility of the SIJ is not only possible,[73–76] but also essential for shock absorption during weight-bearing activities.[77] However, the range of motion (ROM) in the SIJ is small, less than 4 degrees of rotation and up to 1.6 mm of translation.[74,78] Of interest, is the fact that one study[79] found no difference in available ROM between the symptomatic and asymptomatic sides.

It is likely that the movement of the pelvis is in the nature of deformations and slight gliding motions around a number of undefined axes, with the joints of the pelvic ring deforming in response to body weight and ground reaction forces. The amplitude of this motion likely varies among individuals. Motion at the SIJ is facilitated by several features, including the following:

- The fibrocartilaginous surfaces of the innominate facets, which are deformable, especially during weight bearing, when the surfaces are forced together.
- The pubic symphysis—if the innominates are moving at the SIJ, then they must also be moving at their anterior junction, which would allow for an immediate, and almost perfect, reciprocal motion.

No manual diagnostic tests have shown reliability for determining how much an individual's SIJ is moving in either symptomatic or asymptomatic subjects. In contrast to Stureson's study,[78] when Doppler imaging testing has been used to measure stiffness (or laxity) of the SIJ in subjects with and without pelvic pain, it has been shown that asymmetry of stiffness between sides correlated with the symptomatic individual.[80–82] These studies have shown that within the same subject, asymptomatic individuals have similar values for the left and right SIJs, whereas individuals with unilateral posterior pelvic girdle pain had different stiffness values for the left and right sides. Theoretically, when assessing SIJ mobility, a dysfunction at the SIJ can manifest as one of the two types of asymmetries

- If one of the SIJs is hypermobile, the amplitude of motion is increased asymmetrically, and the resistance to motion is decreased on the dysfunctional side.
- If one of the SIJs is hypomobile, the amplitude of motion is asymmetrically reduced, and the resistance to motion is increased on the dysfunctional side.

Thus, the current trend is to focus more on the symmetry, or asymmetry, of the motions palpated or observed.

Anatomical research,[83–85] initiated to determine the source of low back pain, has demonstrated that alterations in the pattern of muscular contraction and the timing of specific muscle activation differ between healthy subjects and those demonstrating symptoms. Furthermore, studies[86] have shown that the strength and endurance of the trunk muscles are important in determining the muscle capacity of individuals. This research has led to theories about the force- and form-closure mechanisms of joints and how stability is necessary at joints for effective load transfer. Based on this knowledge, functional tests of load transfer through the pelvic girdle have been developed[87–89] together with a number of treatment protocols.[90–92] This approach has three physical components (form closure, force closure, and motor control) and one psychological component (emotions).

In upright positions, the SIJ is subjected to considerable shear force as the mass of the upper body must be transferred to the lower limbs via the ilia.[93,94] The body has two mechanisms to overcome this shear force: one dependent on the shape and structure of the joint surfaces of the SIJs (form closure), which is wedge shaped with a high coefficient of friction, and the other mechanism involving generation of compressive forces across the SIJ via muscle contraction (force closure).[94]

Form Closure

Form closure refers to a state of stability within the pelvic mechanism, with the degree of stability dependent on its anatomy, with no need for extra forces to maintain the stable state of the system.[85] The following anatomic structures are proposed to assist with form closure:

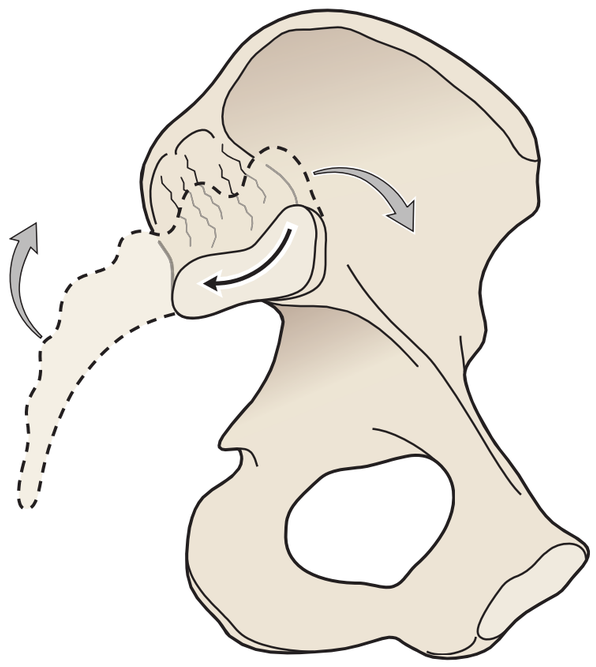

FIGURE 29-5 Sacral nutation.

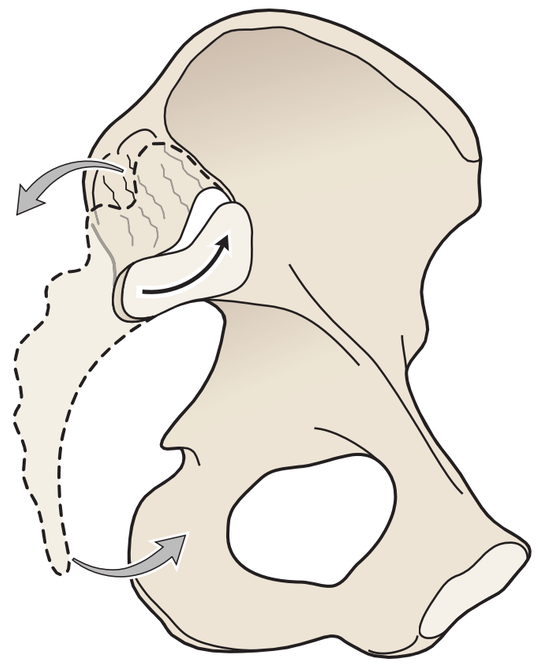

FIGURE 29-6 Sacral counternutation.

- The congruity of the articular surfaces and the friction coefficient of the articular cartilage. Both the coarseness of the cartilage and the complementary grooves and ridges increase the friction coefficient and thus contribute to form closure by resisting against horizontal and vertical translations.[22] In infants, the joint surfaces are very planar, but between the ages of 11 and 15 years, the characteristic ridges and humps that make up the mature sacrum begin to form. By the third decade, the superficial layers of the fibrocartilage are fibrillated, and crevice formation and erosion has begun. By the fourth and fifth decades, the articular surfaces increase irregularity and coarseness and the wedging is complete.[18]
- The integrity of the ligaments.
- The shape of the closely fitting joint surfaces.

According to current research, when the sacrum nutates, or flexes, relative to the innominate (Fig. 29-5), or when the innominate posteriorly rotates relative to the sacrum, the greatest number of ligaments, particularly the interosseous and posterior (dorsal) ligaments, are tightened at the SIJ.[85,95,96] These latter ligaments lie posterior to the joint and approximate the posterior iliac bones when placed under tension.[95] Thus, nutation of the sacrum can be described as the close packed position, or self-locking mechanism, for the SIJ and is, therefore, the most effective position for transferring high loads. This position somewhat conveniently produces a position of lumbar lordosis, which is advocated in many interventions for the lumbar spine.

Just as nutation of the sacrum enhances the self-locking mechanism, counternutation of the sacrum (Fig. 29-6), which occurs during activities, such as the end range of forward bending, sacral sitting, long sitting, and hip hyperextension, reduces the self-locking mechanism.[95]. This position results in a loss of the lumbar lordosis and an increase in intervertebral disk pressure (see Chapter 28).

Using forward bending at the waist as an example, a combination of anterior and outward rotation of both innominates results in the approximation and superior motion of both PSISs, while the sacrum nutates (Table 29-2). After approximately 60 degrees of forward bending, the innominates continue to rotate anteriorly, but the sacrum no longer nutates.[84] If the sacrum remains nutated throughout the forward bending, the SIJ remains compressed and stable. However, if the sacrum is forced to counternutate earlier in the range, as in individuals with tight hamstrings, less compression occurs, thereby increasing the reliance on dynamic stabilization provided by muscles and thus making the SIJ more vulnerable to injury.[84]

Force Closure

Force closure requires intrinsic and extrinsic forces to keep the SIJ stable.[85] These dynamic forces involve the neurological and myofascial systems and gravity. Together, these components produce a self-locking mechanism for the SIJ. Optimum force closure requires the application of just the right amount of force at just the right time, which in turn requires a motor control system that can predict the timing of the load and prepare the system appropriately. The degree of force closure depends on the capability of an individual's form closure and the various loading conditions (e.g., speed, duration, magnitude, and predictability).[97]

TABLE 29-2 Lumbar Motions and Sacroiliac Motions

Lumbar Motion	Innominate Motion	Sacrum Motion
Flexion	Anterior rotation	Nutation, then counternutation
Extension	Slight posterior rotation	Nutation
Rotation	Ipsilateral: Posterior rotation Contralateral: Anterior rotation	Nutates ipsilaterally
Side bending	Ipsilateral: Anterior rotation Contralateral: Posterior rotation	Ipsilateral: Side bends ipsilaterally Contralateral: Side bends contralaterally

In a kinetic analysis of the pelvic girdle, Vleeming et al.[50,95] identified a number of muscles that resist translational forces and which are specifically important to the force-closure mechanism: the erector spinae, gluteus maximus, latissimus dorsi, and biceps femoris (see Chapter 28). Two other muscle groups, an "inner muscle unit" and an "outer muscle unit" also play an important role.[84,86,92] The inner muscle unit consists of the following:

- **Transversus abdominis (TrA).** A study by Richardson et al.[98] found that contraction of the TrA significantly decreases the laxity of the SIJ, and that this decrease in laxity is larger than that caused by a bracing action using all the lateral abdominal muscles. Theoretically, contraction of the TrA produces a force that approximates the ilia anteriorly.[98]
- **The muscles of the pelvic floor.** Hemborg et al.[99] have demonstrated that the pelvic floor muscles coactivate with the TrA during lifting tasks.
- **Multifidus.** Studies[100–102] have reported that the deep fibers of the multifidus become inhibited and reduced in size in individuals with low back and pelvic girdle pain.

The outer muscle unit consists of four systems: the posterior oblique system (latissimus dorsi, gluteus maximus, and thoracolumbar fascia), the deep longitudinal system (erector spinae, deep lamina of the thoracolumbar fascia, sacrotuberous ligament, and biceps femoris), the anterior oblique system (external and internal oblique, contralateral adductors of the thigh, and the intervening anterior abdominal fascia), and the lateral system (gluteus medius–minimus and contralateral adductors of the thigh). The outer muscle unit is proposed to contribute to the force-closure mechanism in the following manner[84]:

- **Posterior oblique system.** The gluteus maximus (see Chapter 19), which blends with the thoracodorsal fascia, and the contralateral latissimus dorsi contribute to force closure of the SIJ posteriorly by approximating the posterior aspects of the innominates. This oblique system is a significant contributor to load transference through the pelvic girdle during the rotational activities of gait.
- **Deep longitudinal system.** This system serves to counteract any anterior shear or sacral nutation forces as well as to facilitate compression through the SIJs. As mentioned in the anatomy section, the long head of the biceps femoris muscle controls the degree of nutation via its connections to the sacrotuberous ligaments.[36]
- **Anterior oblique system.** The oblique abdominals, acting as phasic muscles, initiate movements.[92]and are involved in all movements of the trunk and upper and lower extremities, except when the legs are crossed.[103]
- **Lateral system.** The lateral system functions to stabilize the pelvic girdle on the femoral head during gait through a coordinated action.

CLINICAL PEARL

The stability of the SIJ is a factor of the length and strength of the muscle units, neuromuscular control, and the ability of the sacrum to nutate in all positions of threat. Weakness or insufficient recruitment and/or unbalanced muscle function within the lumbar/pelvic/hip region can reduce the force-closure mechanism, which can result in compensatory movement strategies.[104] These compensatory movement strategies and/or patterns of muscle imbalance may produce a sustained counternutation of the sacrum, thereby "unlocking" the mechanism and rendering the SIJ vulnerable to injury. This unlocked position of the pelvis may also increase shear forces at the lumbar spine and abnormal loading of the lumbar disks.

The sacrococcygeal joint has a limited amount of movement in flexion and extension, ranging from approximately 5–15 degrees in either direction.[105] A posterior rotation (flexion) motion occurs when moving from a standing to a sitting position, which is thought to enable optimal force absorption in the seated position.[16] The reverse occurs when moving from a seated to a standing position.

As alluded to earlier, the sacral positions that correspond to poor sacral biomechanics are very similar to those lumbar spine positions that are unfavorable to spinal stability. Conversely, the positions that enhance sacral stability also enhance lumbar spine stability. As a result, there has been much confusion amongst disciplines when determining whether the SIJ or lumbar spine is the cause of the patient's symptoms. For example, consider the prone on elbows position (see Chapter 28), which nutates the sacrum and increases the lordosis of the lumbar spine. If a patient with either a sacral dysfunction or an intervertebral disk herniation is asked to adopt this position, the symptoms would likely decrease.

EXAMINATION

Most investigators agree that no single test can be used to confirm the diagnosis of SIJ dysfunction because of the complexity of the anatomy and biomechanics and its proximity to other symptom-provoking structures.

Diagnostic physical examination tests that are commonly used to determine a diagnosis include[55]

- direct tenderness;
- soft-tissue examination for zones of hyperirritability and tissue texture changes;
- evaluation of referral zones;
- associated fascial or musculotendinous restrictions;
- abnormal regional length–strength muscle relationships;
- postural analysis;
- true leg length and functional leg-length determination;
- static and dynamic osseous landmark examinations; and
- provocative testing including traditional orthopaedic tests, motion demand tests, and ligament tension tests.

Although traditionally assumed to be reliable and diagnostically useful, none of these tests has ever been validated against an independent criterion standard.[55] As a consequence, controversy exists about which group of tests is the best.

Under the premise that a relationship exists between pelvic asymmetry and low back pain, orthopaedic, osteopathic, and physical therapy tests promote the use of pain provocation (symptom based) tests and static (positional) or dynamic (motion or functional) tests.[1,10,38,84,106–109]

The use of static tests has been questioned,[110–114] although Cibulka et al.[115] found the results from these tests reliable, Levangie[114] found a weak association between standing PSIS asymmetry and low back pain, at least in selected groups. The problems with static testing are

- the high degree of anatomical variability in this area;
- determining whether the asymmetry noted is normal or abnormal;
- determining which side is abnormal; and
- determining whether the asymmetry is too asymmetric or not asymmetric enough. For example, if the right innominate is anteriorly rotated, compared with the left, is it rotated too much, too little, or just the right amount compared with its starting position? Because the starting position is not known, the degree of rotation cannot be assessed.

The dynamic tests do not fare much better. Dreyfuss et al.[55] reported 20% positive findings in one or more of the dynamic (motion or functional) tests in a group of asymptomatic people. The major problem with the dynamic tests is that SIJ motion is small, so it is highly implausible to be able to detect it. An example of a dynamic test is the standing flexion test, which has frequently been used to analyze SIJ mobility and to determine the side of the impairment. The test is performed as follows: Each PSIS is palpated with the thumb placed under it caudally. The patient then bends forward at the waist. Provided there is no impairment in the SIJ or the lower lumbar spine, as the patient bends forward, both thumbs should move superiorly (cranially). If one SIJ joint is "blocked," it moves upward further in relation to the other side.[113] Thus far, reliability studies of the standing flexion test show that it lacks sufficient diagnostic power.[113,116,117] This is shortfall may be because the compression of the joints caused by the sacral nutation in the early to midranges of forward flexion likely limits movement of the SIJ.[118]

Some studies have reported that pain provocation tests have a good interexaminer reliability,[113,119] but they have not been found reliable by others.[15,116] This is likely because the pain provocation tests have only been found reliable in identifying SIJ dysfunction in certain populations, such as patients with posterior pelvic pain during or following pregnancy.[120] Laslett et al.[121] reported that adequate sensitivity (0.88) and specificity (0.78) can be achieved using a clinical prediction rule involving two positive tests of distraction, thigh thrust, compression, and sacral thrust (see Pain Provocation Tests in Special Tests section). The diagnostic process begins with the two tests that have the highest positive predictive value and specificity (distraction test) and negative predictive value and sensitivity (thigh thrust) for identifying SIJ pathology. If these two tests both recreate the patient's SIJ pain (positive), further tests are not indicated. If one or neither of the two tests are positive, the clinician follows the algorithm in Figure 29-7.

As several recent studies have found improved interrater reliability in the diagnosis of low back pain when using a combination of physical examination procedures as opposed to a single model approach,[15,55,113,122,123] it would be logical to assume that a similar approach would work with the SIJ.

Ideally, the diagnosis needs to be based on the results of a thorough biomechanical examination that includes an assessment of load transfer, and pain provocation. Patients with failed load transfer through the pelvic girdle often present with inappropriate force closure, in that certain muscles become overactive while others remain inactive, delayed, or asymmetrical in their recruitment.[124] When approaching SIJ dysfunction it is likely more important to determine why there are symptoms, rather than attempting to identify the specific symptom generating structures.

CLINICAL PEARL

The main objective of SIJ assessment is to determine whether the condition appears to primarily involve[97]

- too much compression occurring from stiff, fibrosed joints or hypertonicity of the global muscles system;
- poor control of loose joints or under-activation of the deep (local) stabilizing muscles system; and
- a combination of too much compression and too little control throughout the lumbopelvic–hip complex.

In most cases, an examination of the pelvic joints is of little use if the lumbar spine and the hip joints have not been previously cleared by examination or intervention, because both of these joints can refer pain to this area and may also profoundly affect the function of the SIJ.

History

A history of low back pain or leg pain, or both, warrants an examination of the lumbopelvic–hip complex. The most common presenting symptoms in patients with SIJ dysfunction are complaints of pain or tenderness over the region of the PSIS.[125–127] The clinician must also determine whether the current problem is a consequence of pregnancy and/or delivery. If so, it is important to ascertain when the symptoms began, what was the nature of the delivery, and how much trauma occurred to the pelvic floor and the abdominal wall.[128]

The following findings are likely to be present with an SIJ dysfunction:[12,55,129,130]

- A history of sharp pain that occurred with a particular activity and that awakens the patient from sleep upon turning in bed. The clinician must ask what kind of bed the patient sleeps in, and what position is most frequently adopted.
- Pain with running, walking, ascending or descending stairs, or hopping or standing on the involved leg.
- Pain with forward bending of the trunk and pain with standing hip flexion.

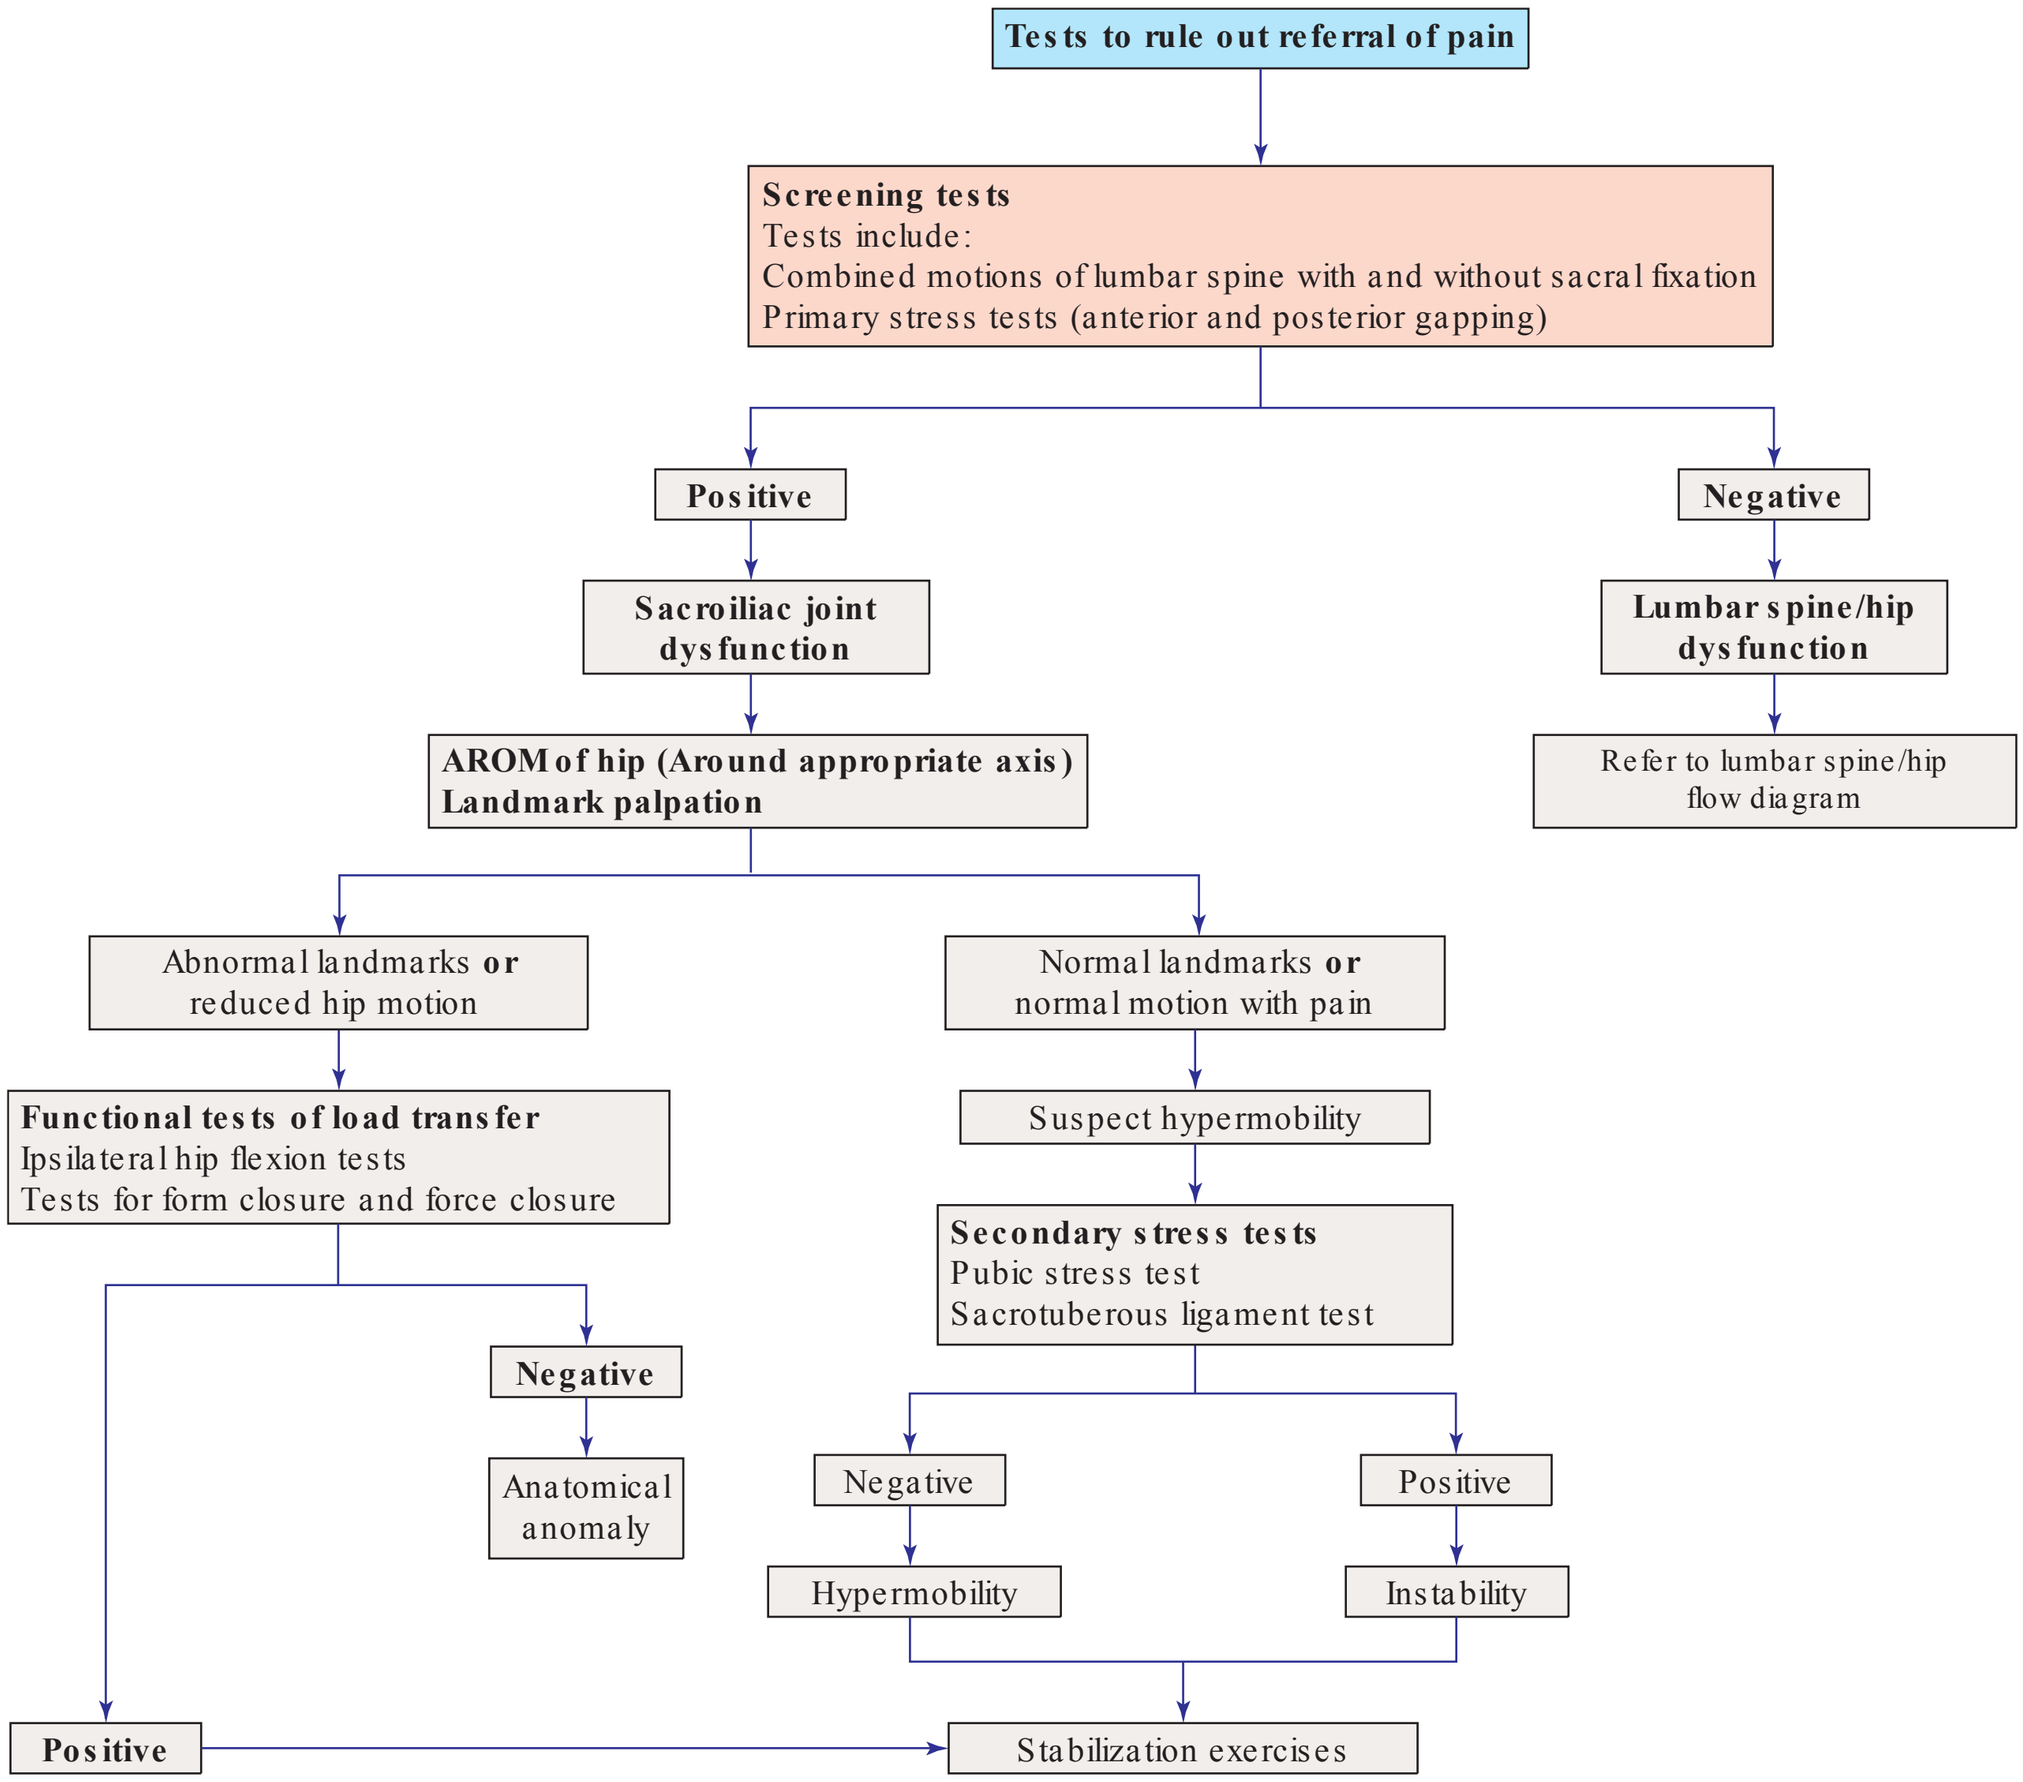

FIGURE 29-7 Decision-making algorithm for the SIJ.

- Pain with transitional movements such as rising to stand from a sitting position or getting in and out of the car.
- Pain with a straight-leg raise at, or near, the end of the range (occasionally early in the range when hyperacute).
- Pain and sometimes limitation on extension and ipsilateral side bending of the trunk.
- Pain that is worsened with long periods of sitting or standing if the lumbar lordosis is not maintained.

The clinician must determine the exact location of the pain/dysesthesia and whether it is localized or diffuse, and its quality (see Chapter 4). If the symptoms do radiate, the clinician must determine how far down the limb or limbs the symptoms are felt, or whether the symptoms radiate into the abdomen or thorax.[128]

Finally, the clinician should ask the patient if there have been any adjunctive diagnostic tests (i.e., x-ray, computed tomography, or magnetic resonance imaging), or any laboratory tests.

Systems Review

Given the number of visceral organs in the vicinity of the SIJ, the clinician must complete a thorough systems review to rule out a visceral source for the symptoms. A Cyriax scanning examination (see Chapter 4) should be performed on any patient who presents with an insidious onset of pelvic pain. The scanning examination, which includes the primary stress tests (anterior and posterior distraction), can be used to help detect sacroiliitis resulting from microtraumatic arthritis, macrotraumatic arthritis, or systemic arthritis (e.g., ankylosing spondylitis, Reiter's syndrome), or the more serious pathologies grouped under the sign of the buttock (see Chapter 19). Primary breast, lung, and prostate cancers are among the most common cancers to metastasize to the axial skeleton, including the pelvic ring.[131] A further source of sacral pain can be a stress fracture of the sacrum, which can be associated with a wide range of extrinsic and intrinsic risk factors (see "Intervention Strategies"), and an equally wide range of symptoms and signs.[132]

Tests and Measures

As previously mentioned, in order to rule in or rule out SIJ dysfunction, a thorough musculoskeletal examination of the low back, the pelvis, the hips, and the remainder of the lower extremities, including a full neurologic evaluation must be performed.

Observation

T e observation should begin as the patient enters the treatment area to assess the impact the patient's condition has on gait. As described in chapter 6, there should be minimal deviation of the head in either plane and no deviation of the pelvis in the coronal plane relative to the lumbar spine and hip (Trendelenburg sign). Asymmetry in stride length and time spent in each phase of the gait cycle can be indicative of impairments within the lumbopelvic hip complex.[128] In addition, an avoidance of the normal heel impact at initial contact may indicate an attempt by the patient to reduce the ground reaction forces and resultant joint loading.

Observation should also include an overall assessment of posture to check for the presence of asymmetry (see Chapter 6). T e primary spinal curves should be maintained (i.e., gentle even lumbar lordosis, thoracic kyphosis, and cervical lordosis), and there should be no kinks, shifts, hinges, or transverse plane rotations in the entire spinal curve.[128] T e clinician should observe the degree of tilt at the pelvis. T e question of cause and effect should be raised. An anterior pelvic tilt, which occurs when the anterior-superior iliac spine (ASIS) moves anteriorly and inferiorly, causes hip flexion and an increase in the lumbar lordosis (extension) and thoracic kyphosis. T e anterior pelvic tilt results in a stretching of the abdominals and the sacrotuberous, SI, and sacrospinous ligaments, and an adaptive shortening of the hip flexors, the hamstrings, and the erector spinae. In contrast, a posterior pelvic tilt, which occurs when the PSIS moves posteriorly and inferiorly, results in lengthening of the hip flexors, the hamstrings, and the erector spinae, and adaptive shortening of the abdominals and the gluteals.

A lateral pelvic tilt results in opposite motions at each side of the pelvis. T e pelvic motion is defined by what is occurring at the iliac crest of the pelvis that is opposite the weight-bearing extremity/side of the pelvis that is moving. A lateral pelvic tilt may be caused by scoliosis with ipsilateral lumbar convexity, a leg-length discrepancy, or shortening of the contralateral quadratus lumborum. T is position results in adaptive shortening of the ipsilateral hip abductors and contralateral hip adductors, and weakness of the contralateral hip abductors. A lateral pelvic tilt is not the same as a pelvic shift. A pelvic shift results in extension of the hip and extension of the lower lumbar spinal segments and is often seen with slouched or relaxed postures.

T ere appears to be a strong correlation between the position of the pelvis and the forward head.[133] If the pelvic landmarks are asymmetric, and the patient has a forward head, the clinician should attempt to correct the forward head. If the attempted correction of the forward head worsens the pelvic asymmetry and increases the symptoms, the intervention should be aimed at correcting the asymmetry. If the attempted correction of the forward head improves the pelvic asymmetry and the symptoms, the subsequent intervention should be aimed at correcting the forward head.[134]

CLINICAL PEARL

The pelvic crossed syndrome (see Chapter 28) produces an increase in anterior tilt accompanied by an increase in lumbar lordosis.

Hip Range of Motion

T e ROM of the hip, including internal and external rotation, is performed to help rule out pain referred from the hip joint. Although a unilateral limitation of hip motion, in which one of the motions is unequal between the left and right sides, has been observed in patients with disorders of the SIJ,[76,135–137] the evidence to demonstrate whether hip motion is limited in patients with signs of SIJ dysfunction is inconclusive. LaBan et al.[64] noted asymmetry in hip abduction and external rotation in patients with inflammation of the SIJs. Dunn et al.[138] reported limited hip mobility in patients with infection of the SIJ; however, no mention was made as to which movements were limited.

Others have described cases in which patients with low back pain had unilateral, limited internal hip rotation and excessive external hip rotation, and also exhibited signs of SIJ dysfunction. A recent study by Cibulka et al.[135] attempted to determine whether a characteristic pattern of hip ROM existed in patients with low back pain, and whether those classified as having SIJ dysfunction have a different pattern of hip ROM compared with those with unspecified low back pain. T e study found that patients with low back pain, who had signs suggesting SIJ regional pain, had significantly more hip external than internal rotation ROM on one side. T e authors concluded that identifying unilateral hip ROM asymmetry in patients with low back pain might help in diagnosing SIJ regional pain.[135] Hip ROM and its relation to lumbar and pelvic motion can be assessed using the one-leg stand test, also known as the stork test or Gillet test.

One-Leg Stand Test. T e patient is positioned in standing and is then asked to stand on one leg, and to flex the contralateral hip and knee towards the waist. T e clinician observes the effort required and the ability to perform the task. T e pelvis should not anteriorly/posteriorly/laterally tilt, nor rotate in the transverse plane as the weight is shifted to the supporting limb.[128] T e test is then repeated on the opposite side. Once the patient has performed this maneuver several times, the clinician kneels behind the patient and, using the thumb of one hand, palpates the PSIS, and the thumb of the other hand to palpate the sacrum at either S2 or the ipsilateral ILA. T e patient is asked to repeat the test while the clinician palpates. A small amount of posterior rotation of the innominate during this maneuver should be felt, and the quality and amplitude should be symmetrical between left and right sides.[128]

Lumbopelvic Range of Motion

Forward Bending. T e patient is positioned in standing and is asked to bend forward at the waist while the clinician

observes and palpates. Forward bending at the waist results in a posterior displacement of the pelvic girdle which, in turn, shifts the center of gravity (COG) behind the pedal base such that slight plantar flexion of the talocrural joint occurs.[139] When the leg lengths are equal, the sacrum should nutate bilaterally and symmetrically relative to the innominates and remain nutated throughout the forward bending motion as the pelvic girdle flexes at the hip joints.[118] The innominate should remain posteriorly rotated relative to the sacrum throughout the forward bend. When the pelvis unlocks, the innominate can be felt to rotate anteriorly relative to the ipsilateral sacrum.[87,140] There should be a symmetry of the paravertebral fullness between the thorax and the pelvic girdle so that it is equal on both sides of the spinal column. As the patient returns to the standing position, the sacrum should remain symmetrically nutated until the erect posture is reached. There is no relative anterior or posterior rotation between the innominates during forward bending, but both should travel an equal distance as the pelvic girdle anteriorly tilts.[139] The forward bending should be repeated several times to note the consistency/inconsistency of any positive findings and the ease with which the patient is able to bend forward repeatedly.[128] A positive test for inadequate load transfer is if there is a lack of anterior pelvic tilt, excessive flexion of the thoracolumbar spine, and any twisting that occurs in the pelvic girdle.[97] Although asymmetry of motion of the innominate during forward bending is a positive finding, it is not indicative of any specific dysfunction of the SIJ.

Backward Bending. The patient is positioned in standing and is asked to bend backward at the waist while the clinician observes and palpates. Backward bending at the waist results in an anterior displacement of the pelvic girdle which, in turn, shifts the COG in front of the pedal base such that slight dorsiflexion of the talocrural joint occurs.[139] When the leg lengths are equal, the sacrum should counternutate bilaterally and symmetrically relative to the innominates and remain counternutated throughout the backward bending motion as the pelvic girdle extends symmetrically at the hip joints.[118] The lumbar spinal segments should extend symmetrically without shifting or hinging, and the innominate should remain posteriorly rotated relative to the sacrum as the pelvic girdle tilts posteriorly throughout the backward bend. As the pelvis unlocks, the innominate can be felt to rotate anteriorly relative to the ipsilateral sacrum. Even though the pelvic girdle is tilting posteriorly, it is the relative motion between the innominate and the sacrum that is important to assess.[128] As the patient returns to the standing position, the sacrum should remain symmetrically counternutated until the erect posture is reached. There is no relative anterior or posterior rotation between the innominates during forward bending, but both should travel an equal distance as the pelvic girdle posteriorly tilts.[139] The backward bending should be repeated several times to note the consistency/inconsistency of any positive findings and the ease with which the patient is able to bend backwards repeatedly.[128] A positive test for inadequate load transfer is if there is a lack of posterior pelvic tilt, excessive extension of the thoracolumbar spine, and any twisting that occurs in the pelvic girdle.[97]

Side Bending. The patient is positioned in standing and is asked to side bend to the right and then to sidebend to the left while the clinician observes and palpates. Right side bending of the body is initiated by displacing the upper legs/pelvis to the left so that the right femur abducts and the left femur adducts, thus maintaining the COG within the pedal base.[139] The apex of this lateral bending curve should be at the level of the greater trochanter, and the body should remain in the coronal plane. The lumbar spinal segments should sidebend symmetrically without shifting or kinking. At the pelvis, during side bending, the left innominate posteriorly rotates relative to the right innominate, and the sacrum rotates to the left while the lumbar spine side bends to the right.[139] The reader should be able to extrapolate what happens during left side bending.

Landmark Palpation

The palpation of landmarks can be used to locate areas of tenderness rather than for detecting pelvic asymmetry, because as asymmetry of pelvic landmarks is the norm, "positive" findings are likely to be misleading.[114] The various landmarks of the pelvis are palpated with the patient positioned standing, sitting, and lying (see Figs. 29-8 and 29-9).

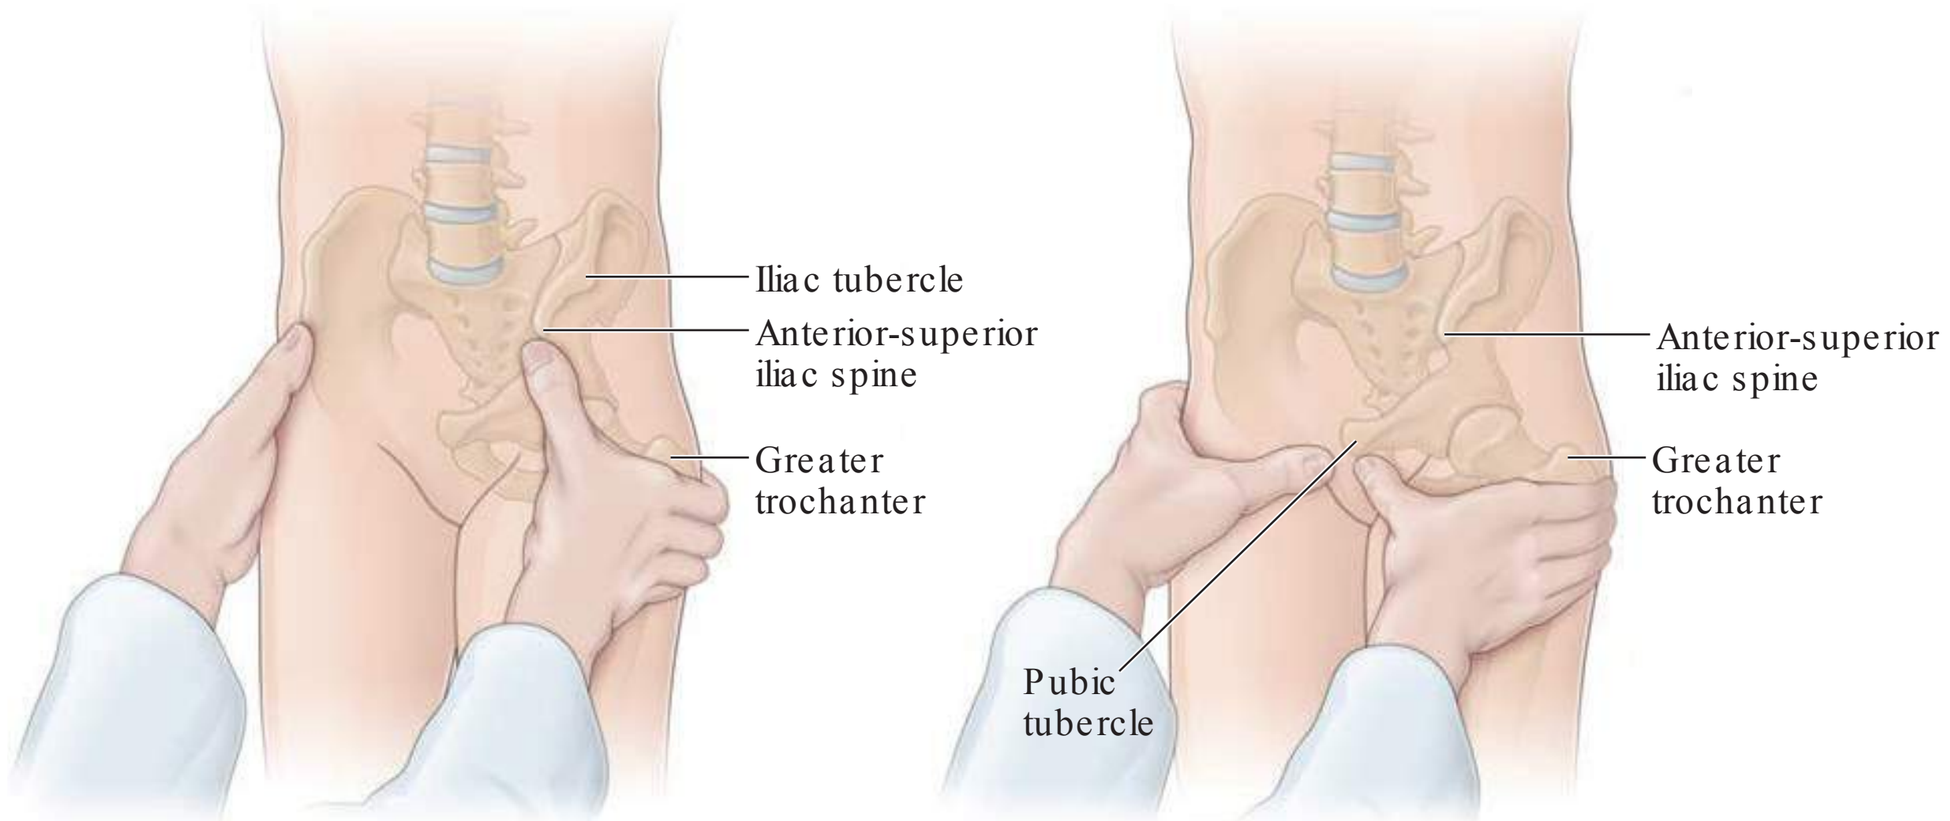

FIGURE 29-8 Palpation of the hip and pelvis.

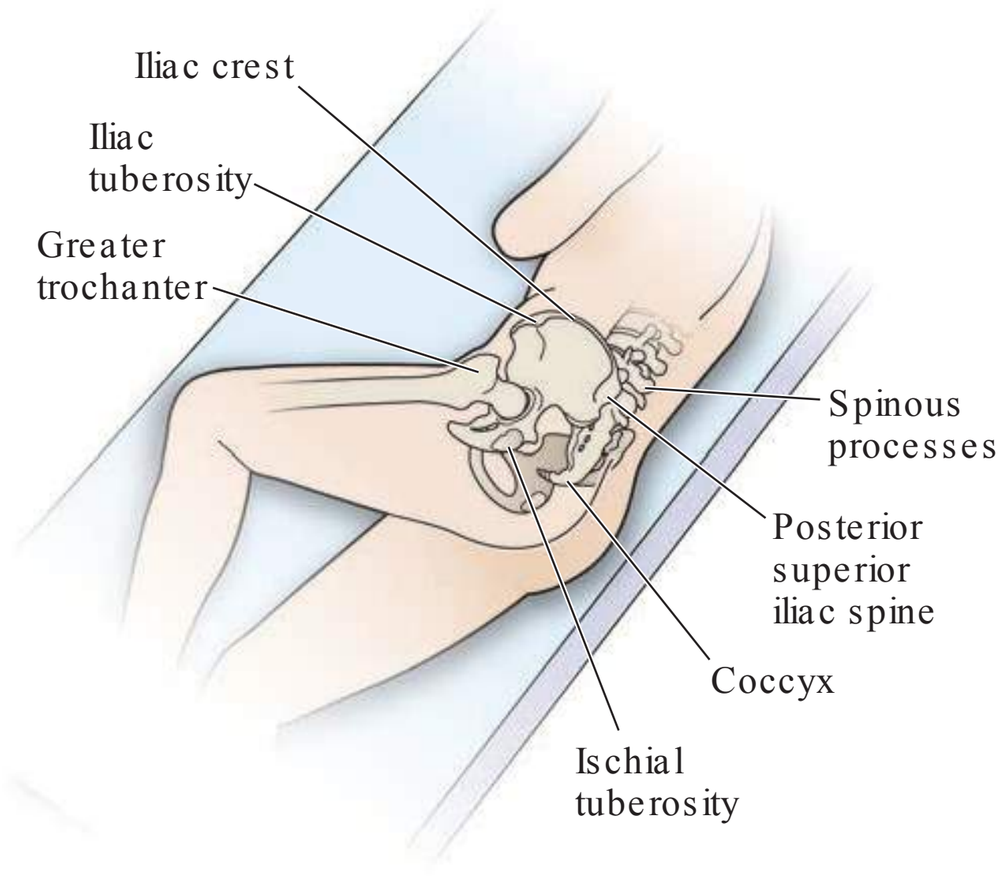

FIGURE 29-9 Bony landmarks.

CLINICAL PEARL

An altered positional relationship within the pelvic girdle should only be considered positive if a mobility restriction of the sacroiliac joint or pubic symphysis, or both, is also found.

The following landmarks and structures are palpated with the patient standing:

- Iliac crest. The iliac crests on both sides are located using the medial aspects of the index fingers. The crest heights should be level.
- Anterior-superior iliac spine (ASIS). These structures are located anteriorly to the iliac crests. Tenderness of the ASIS may indicate a so-called hip pointer injury or injury to the inguinal ligament. An inferior ASIS relative to the other side may indicate a rotated innominate.[8] According to osteopathic doctrine, if the innominate is anteriorly rotated in the supine position, the leg will be longer on that side, but if posteriorly rotated, the leg will be shorter.[8] However, a study by Levangie[114] found that pelvic asymmetry was not positively associated with low back pain in any way that seemed clinically meaningful. It has been suggested to assess the ASIS in sitting versus standing, but there are no reliable studies to recommend this method.
- Posterior-superior iliac spine (PSIS). These structures are located posteriorly to the iliac crests and approximately 2–3 cm beneath the dimples of the lumbar spine and level with the S2 spinous process. Slightly medially and distal to the PSIS are the SIJs. To assess the levels of the PSIS relative to the opposite side, the clinician hooks the thumbs under both PSIS. A superior PSIS relative to the other side may indicate a rotated innominate.[8] A study by Levangie[114] found that although pelvic asymmetry was not positively associated with low back pain in any way that seemed clinically meaningful, asymmetry of PSIS landmarks showed some evidence of a weak positive association with low back pain. This would indicate that the test does not qualify as a screening tool. PSIS asymmetry can also be assessed similarly in sitting, but the findings from Levangie[141] indicate that this test provides little value during the examination and does not qualify as a screening tool.
- Pubic symphysis and pubic tubercles. The pubic tubercles are lateral to the pubic symphysis.
- Posterior (dorsal) ligament. This strong ligament is situated in a deep depression between the sacrum and ilium.
- Ischial tuberosity and the sacrotuberous ligament (medial to the tuberosity). According to osteopathic doctrine, the sacrotuberous ligament is firm on the side of an anteriorly rotated innominate, and taut on the side of a posteriorly rotated innominate.[8] The patient is positioned prone and the clinician stands at the patient's side. With the heel of the hands, the clinician locates the ischial tuberosities through the soft tissue at the gluteal folds. Then, with the thumbs, the clinician palpates the inferomedial aspect of the ischial tuberosities. From this point, the clinician slides the thumbs superolaterally and palpates the sacrotuberous ligament. The clinician then compares the relative tension between the left and right sides.
- Sacral sulcus (sacral base). The sacral sulcus (dimple) is located over the sacral base. From the PSIS, the clinician moves in a thumb width and then up a thumb width.
- Inferior lateral angle (ILA). These structures are level with the prominent part of the tailbone.
- L5 segment. The clinician palpates medially along the iliac crest. L5 is usually level with the point at which the palpating finger begins to descend on the crest. The L5–S1 zygapophyseal joints are located halfway between the L5 spinous process and the ipsilateral PSIS.
- Lumbosacral angle. An increased or decreased lumbosacral angle (the angle the sacrum makes with the lumbar spine) on one side may indicate a rotated innominate. Although very difficult to measure without radiographs, the normal lumbosacral angle is approximately 140 degrees from the vertical.
- S2 segment. S2 is normally level with the PSIS.

Functional Tests of Load Transfer through the Pelvis

Whereas the results from static landmark palpation tests can be misleading, palpating landmarks during dynamic activities are a better test of function, especially when used as a comparison with the other side.

Forward Bending. This test assesses the ability of the pelvis to tolerate both vertical and horizontal shear forces, and its ability to control forward sagittal rotation during forward bending of the trunk. The patient is positioned in standing and is asked to bend forward at the waist while the clinician observes the lumbopelvic hip rhythm (Fig. 29-10). A positive test for inadequate load transfer is if there is a lack of anterior pelvic tilt, excessive flexion of the thoracolumbar spine, and any twisting that occurs in the pelvic girdle.[97]

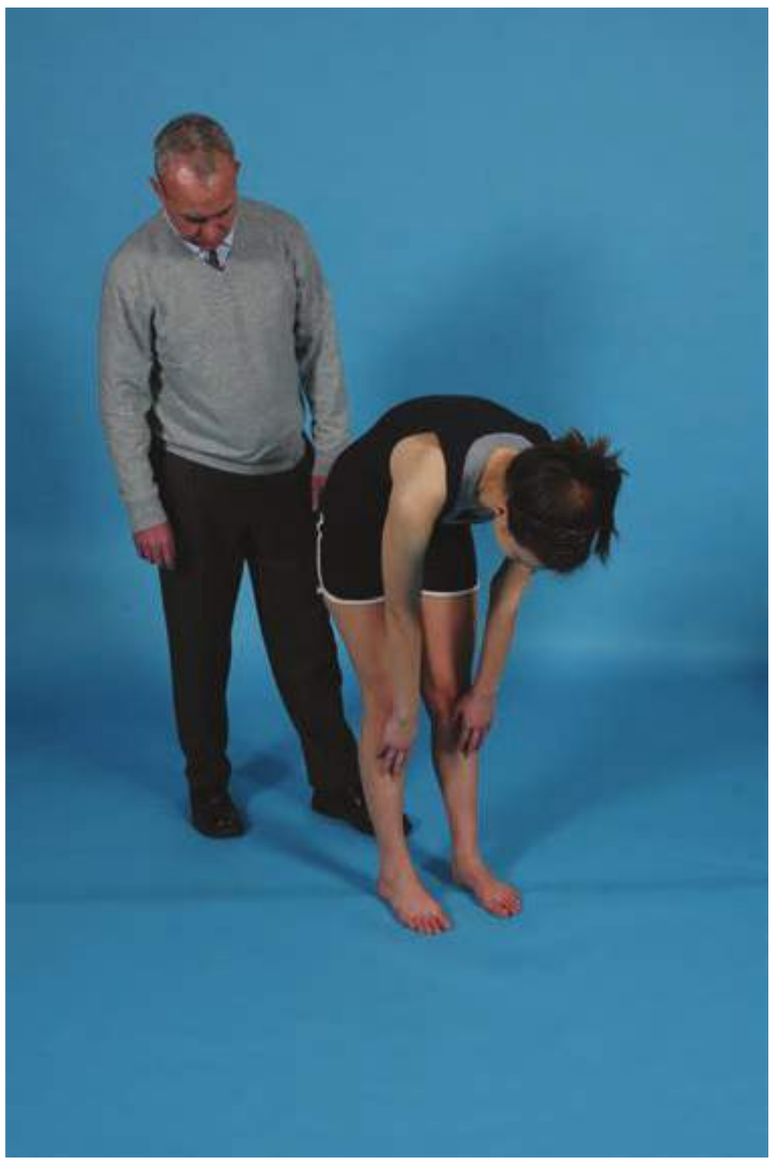

FIGURE 29-10 Forward bending test.

Functional Squat. The patient is asked to stand with feet shoulder width apart and is then asked to lower and raise the body using a combination of hip and knee flexion while maintaining the same thoracopelvic orientation. During the squat, the ankles should dorsiflex, the feet should pronate, and the pelvic girdle should tilt anteriorly on the femoral heads.[139]

Alternating Unilateral Standing. The patient is positioned in standing and is then asked to stand on the uninvolved leg (the side opposite the symptoms where possible) while using the clinician for balance. The position should be maintained for up to 30 seconds or until the pain is reproduced at which point, the patient is asked to transfer the weight-bearing through the opposite leg. As before, the position should be maintained for up to 30 seconds or until the pain is reproduced. Positive findings for this test include an inability to maintain the unilateral stance for 30 seconds and an inability to shift weight from one leg to the other without pain.

This test can be used with a patient who reports difficulty walking or who demonstrates an antalgic gait. This type of patient is reluctant to bear full weight on the impaired side of the pelvis and will use a variety of compensatory strategies to prevent loading of the SIJ. On many occasions, the use of an SI belt in this situation can provide significant relief and can be used to confirm the findings. For example, if the test is found to be positive, an SI belt is fitted to the patient and the patient is asked to repeat the test. If the belt enables the patient to perform the test, or reduces the symptoms during the test, a trial period of using the belt is advised.

Specific Tests for Form Closure. The patient is positioned in supine with the hips and the knees slightly flexed or supported by a bolster. Since muscle activation can compress the SIJ, the patient is instructed to relax completely during the test. The following description is for a test of the right side of the sacrum. With the right hand, the clinician grasps the

FIGURE 29-11 Grasping the right ASIS and right innominate.

anterior aspect of the patient's right innominate and ASIS (Fig. 29-11). The clinician then slides his or her left hand under the left side of the patient's lumbar spine and palpates the left sacral sulcus, just medial to the PSIS with the index and long finger to monitor translation between the sacrum and the innominate. From this position, the clinician stabilizes the left sacral base and sulcus with the left hand, and pushes the right innominate down toward the bed using the right hand, in a variety of directions to determine the plane of the SIJ. Slight motion should be felt before a ligamentous end-feel is reached. Once the plane of motion is determined, the stiffness for A-P translation of the SIJ is compared bilaterally. There should be no pain or asymmetry. A loss of motion or pain reproduction compared with the contralateral side indicates dysfunction. To test the ability of the pelvic girdle to resist vertical translation, a superoinferior force is applied to the innominate through the distal end of the femur or through the ischial tuberosity (Fig. 29-12). Again, slight

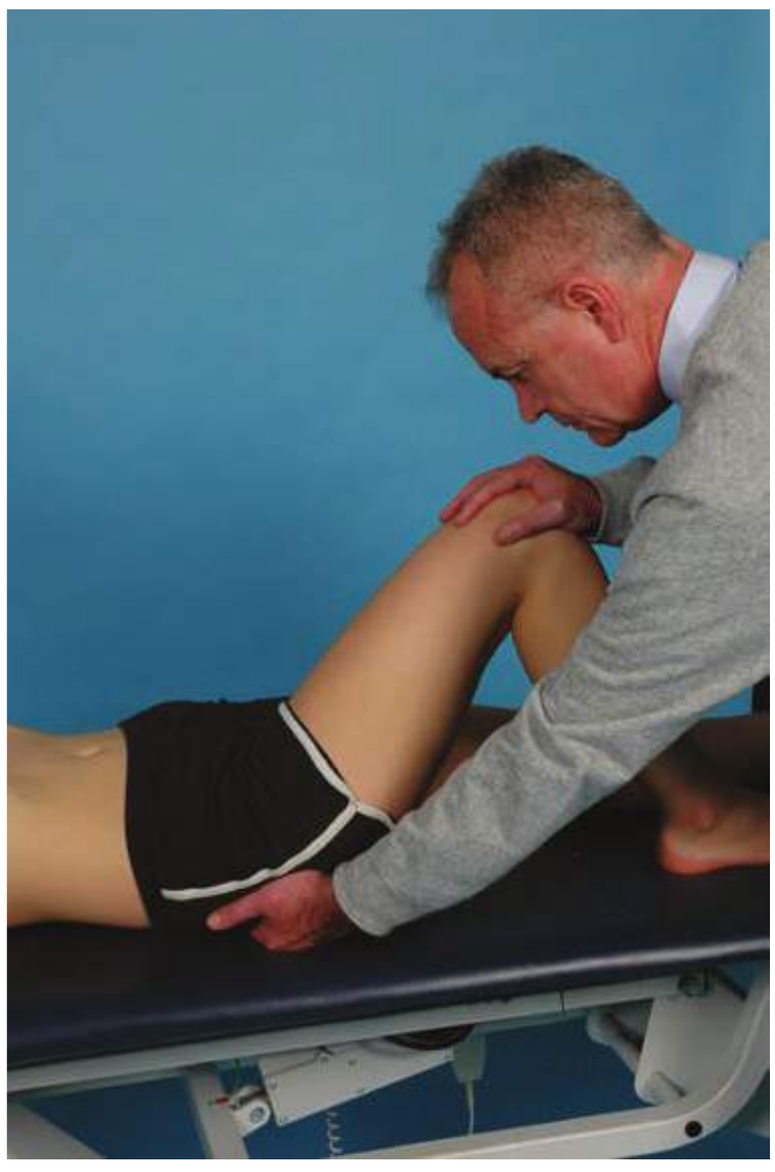

FIGURE 29-12 Form-closure test–superoinferior force.

motion should be felt (although a little more than with the previous test) before a solid ligamentous end-feel is reached. T e stiffness for superoinferior translation of the SIJ is compared bilaterally. T ere should be no pain or asymmetry. A loss of motion or pain reproduction compared with the contralateral side indicates dysfunction.

Prone Knee Bend. T is test help to determine if a pelvic dysfunction needs to be addressed in patients with hamstring strains in order for full return to function and decreased risk of recurrence, as well as helping the clinician differentiate lumbar spine dysfunctions from pelvic girdle dysfunctions.[128] T e patient is positioned in prone and is asked to bend one knee to 90° of flexion. T e test is then repeated on the other side. T e patient is asked to comment on the amount of effort required to initiate the movement between both sides and whether one leg feels heavier than the other. If the patient reports that one side is harder to bend/lift than the other, the clinician palpates the PSIS of the involved side (heavier leg) using the thumb of one hand, and palpates the sacrum at either S2 or the ipsilateral ILA with the thumb of the other hand, and asks the patient to repeat the test. T e other leg is then tested. During the palpation, the clinician notes the presence of any abnormal intrapelvic torsion and compares it to the other side. If abnormal intrapelvic torsion is palpated on the involved side, the clinician applies a compression force across the pelvis, by placing each hand on opposite sides of the pelvis and pushing the hands towards each other. While maintaining the compression force, the patient is asked to bend the knee on the involved side and to note whether the task requires less effort than before. If the compression force is felt to make the task easier, this would tend to indicate that there is a form closure dysfunction.

Specif c Tests for Force Closure and Motor Control. T e active straight-leg raise (ASLR) test and the reverse ASLR have been recommended as tests to help identify nonoptimal stabilization of the pelvic girdle and the ability to transfer loads between the lumbosacral spine and legs.

- T e Active Straight-Leg Raise (ASLR). T e ASLR demonstrates the patient's ability to transfer the load to the pelvis in the supine line position and has been validated for reliability, sensitivity, and specificity of pelvic girdle pain after pregnancy.[88,89,142] It can also be used to identify nonoptimal stabilization strategies for load transfer through the pelvis.[97] T e test is performed with the patient in supine with both legs straight. T e patient is instructed to lift one leg off the table without bending the knee, and the clinician observes the strategy used (Fig. 29-13). T e leg should flex at the hip joint, and the pelvis should not rotate, side bend, flex, or extend relative to the lumbar spine. T e ribcage should not draw in excessively (over activation of the external oblique muscles), nor should the lower ribs flare out excessively (over activation of the internal oblique muscles), or the abdomen bulge (Valsalva). If the patient is unable to perform this maneuver correctly, or the maneuver causes pain, the test is repeated with the clinician applying a compression force through the pelvis (anterior then posterior) directed at the SIJs (form closure) (Fig. 29-14). If the patient is then able to perform the ASLR, the test

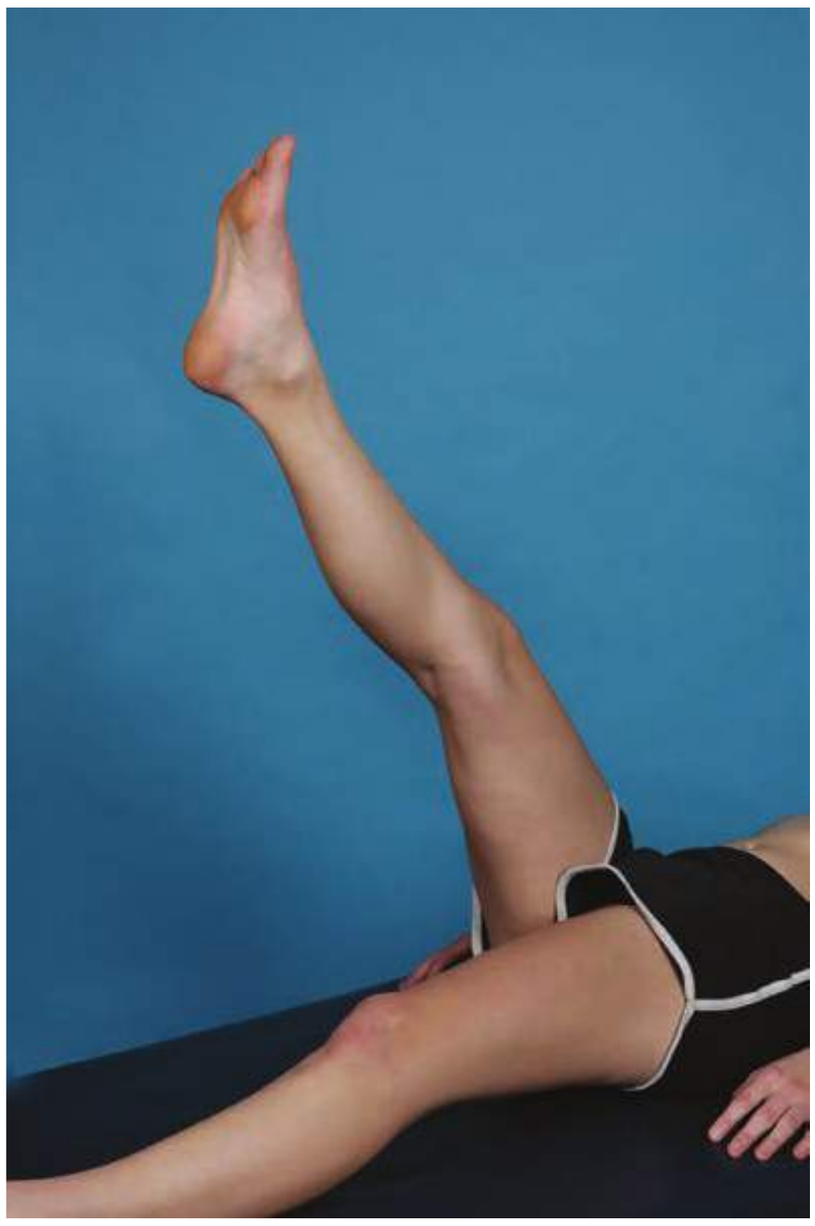

FIGURE 29-13 Active straight-leg raise (ASLR).

is considered positive. If the application of anterior compression enabled the patient to perform the ASLR, an exercise program emphasizing the isolation, timing, and strength of the TrA is recommended. If the application of posterior compression enabled the patient to perform the ASLR, an exercise program emphasizing the isolation,

FIGURE 29-14 Active straight-leg raise (ASLR)—second part.

timing, and strength of the multifidus is recommended. Slight modifications to the test can be used to help confirm the diagnosis.

- One knee is flexed, and the patient is asked to perform a straight-leg raise with the other leg. Flexing the contralateral knee to the straight-leg raise has the effect of relaxing the lumbar spine while maintaining the counternutation on the ipsilateral side. If this maneuver decreases the pain, a muscle imbalance could be present (quadratus lumborum, multifidus, etc.).
- T e patient is asked to lift one shoulder off the bed against manual resistance from the clinician while performing the straight-leg raise on the contralateral side. T is maneuver tests the ability of the anterior oblique system (force closure).

Assessment findings that indicate excessive compression include[97]

- reduced movement on active mobility tests;
- an ASLR test result that does not change or that worsens with compression;
- palpable hypertonicity in specific muscles and/or nonoptimum patterns of muscle recruitment during movement or in response to verbal cueing.

Assessment findings that indicate poor motion control include[97]

- an ASLR test result that improves with compression;
- nonoptimum pattern of muscle recruitment in response to verbal cueing; and
- loss of joint position during functional load transfer tests.
- T e reverse ASLR. T is test is performed with the patient in prone with the patient performing active hip extension with the leg straight under three progressive conditions
  - T e patient performs hip extension with the leg straight (Fig. 29-15)
  - T e patient performs hip extension with the leg straight with the clinician applying manual compression to the innominate bones (form closure) (Fig. 29-16).
  - T e patient performs hip extension with the leg straight with the clinician resisting extension of the contralateral medially rotated upper extremity (force closure).

FIGURE 29-15 Reverse ASLR.

FIGURE 29-16 Reverse ASLR—second part.

No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

CLINICAL PEARL

Theoretically, with the ASLR and reverse ASLR tests, if function improves when force closure stabilization is used, exercise will likely benefit the patient. If during these tests, form closure seems to provide benefit, the prescription of an SI belt is recommended.

Special Tests

A number of special tests have been designed for the SIJ, most of which attempt to stress various parts of pelvic complex and must, therefore, be used with caution.

Pain Provocation Tests

Pain provocation tests have shown good intertester reliability,[143,144] especially when combined test results are considered.

Sacroiliac Joint Stress Tests. A positive stress test is one that reproduces unilateral or bilateral SI pain, either anteriorly or posteriorly.[145] A positive stress test indicates the presence of inflammation but does not give any information as to the cause. If either test is positive in a patient who has recently fallen, there is a possibility that a fracture of the pelvis exists.[146] Some of the stress tests are considered to have fair reliability and moderate specificity.

Anterior Sacroiliac Joint Stress *T*est. T e anterior stress test, also called the distraction test, is performed with the patient supine. T e clinician stands to one side of the patient and, crossing the arms, places the palm of the hands on the patient's ASIS (Fig. 29-17). T e crossing of the arms ensures that the applied force is in a lateral direction, thereby gapping the anterior aspect of the SIJ. T e stress is maintained for 30 seconds once an end-feel is obtained. T e procedure stresses the anterior (ventral) ligament and compresses the posterior aspect of the joint. A positive test is one in which the patient's groin or SIJ pain is reproduced anteriorly, posteriorly, unilaterally, or bilaterally.

T e anterior distraction test and its posterior counterpart (see next section) are believed to be sensitive for severe

FIGURE 29-17 Anterior sacroiliac joint stress test.

arthritis or anterior (ventral) ligament tears of the SIJ,[145] although they have been shown to be poorly reproducible.[113]

Posterior Sacroiliac Joint Stress Test. The posterior stress test, also called the compression test, is performed with the patient in the supine or side-lying position. The clinician, standing behind the patient, applies a medial force to both innominates, using both hands (Fig. 29-18). The stress is maintained for 30 seconds once an end-feel is obtained. The procedure creates a medial force that tends to gap the posterior aspect of the SIJ while compressing its anterior aspect. The reproduction of pain over one or both of the SIJs is considered a positive test. The test also indirectly assesses the ability of the sacrum to counternutate.

Thigh Thrust (Sacrotuberous stress test, 4 P test, POSH test, Oostagard test). This is maneuver should only be performed on a normal hip joint. The patient is positioned in supine, and the resting symptoms are assessed. The clinician stands on the painful side. The clinician flexes the hip on the painful side to 90 degrees and neutral adduction and then places his or her hand under the sacrum to form a stable base for the sacrum. The clinician then applies a downward pressure through the femur to force a posterior translation of the innominate, and the patient's symptoms are assessed (Fig. 29-19). A positive test is a reproduction of the patient's symptoms (posterior to the hip or near the SIJ) on the side of the loaded femur. This is is one of the few SI tests that exhibits a fair sensitivity. In a

FIGURE 29-18 Posterior sacroiliac joint stress test.

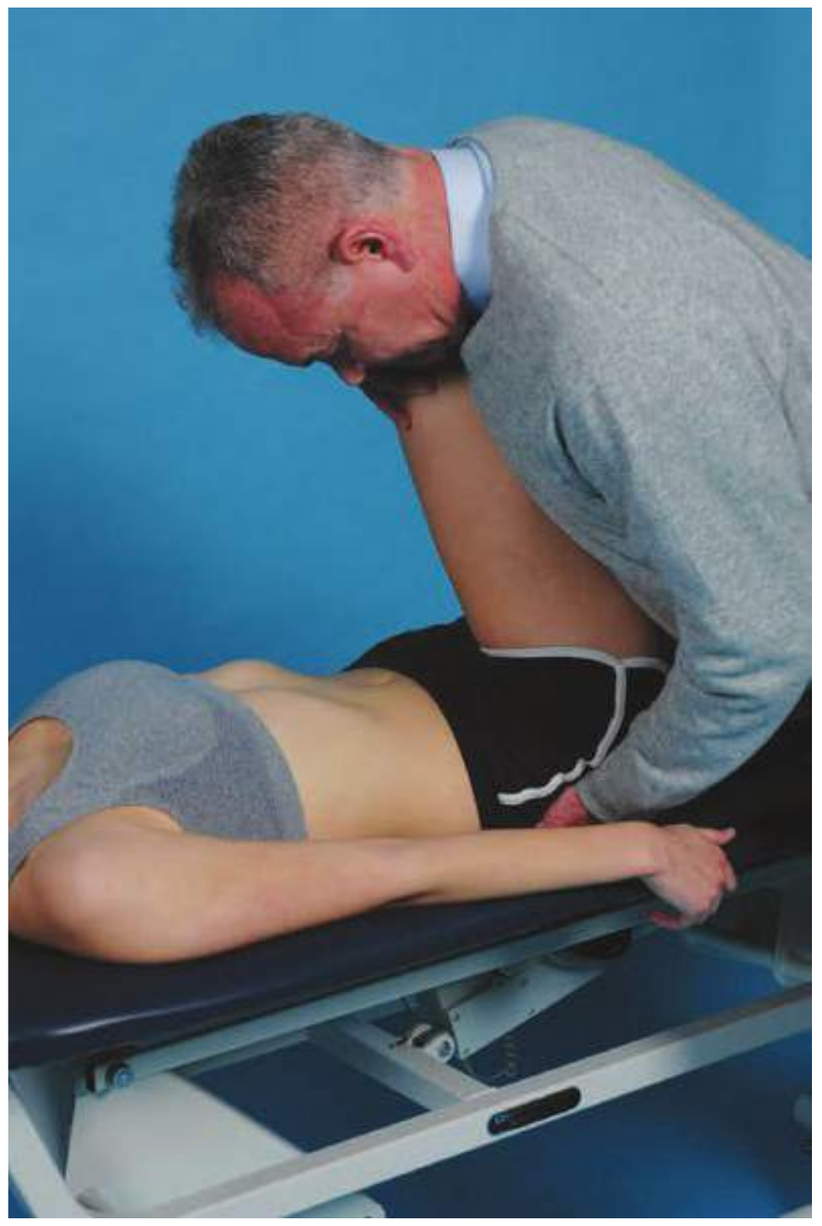

FIGURE 29-19 Thigh thrust (Sacrotuberous stress test, 4 P test, POSH test, Oostagard test).

study by Broadhurst and Bond,[147] the test was found to have a sensitivity of 80% and a specificity of 100%.

Sacral Thrust Test. The patient is positioned prone on a firm surface, and the clinician stands at the patient's side. With one hand, the clinician palpates the inferior aspect of the sacrum in the midline (second or third spinous process of the sacrum) and reinforces this hand with the other. The clinician then applies an anterior force at S3 (Fig. 29-20) vigorously and repeatedly (up to six thrusts), and the reproduction of symptoms is noted. The test is considered positive if the pain is reproduced over the SIJs or the posterior (dorsal) SI ligament, or both.[148] In a study by Laslett et al.,[119] this test was found to have a sensitivity of 63% and a specificity of 75% (LR+ 2.5; LR− 0.49) suggesting that the test provides only marginal diagnostic value when used in isolation.

Laslett et al.[121] reported that when any two of the four aforementioned pain provocation tests are positive, the SIJ is a source of pain (Fig. 29-21). These patients do not typically do well using an SI belt, nor do they respond at this stage of their recovery to exercises that further compress the pelvis.[128]

Posterior (dorsal) SI ligament. The patient is positioned in prone, with the head in neutral position and the arms by the sides. The clinician palpates along the length of the ligament from just medial to the lateral sacral crest at S3 and S4 to the lateral aspect of the PSIS and the inner lip of the iliac crest, noting any tenderness. While continuing to palpate the ligament with one hand, the clinician then applies a counter nutation force to the sacrum and notes if there are any increases in local pain.

Posterior Pelvic Pain Provocation Test. The posterior pelvic pain provocation test, as described by Ostgaard et al.,[149] is

FIGURE 29-20 Sacral thrust test.

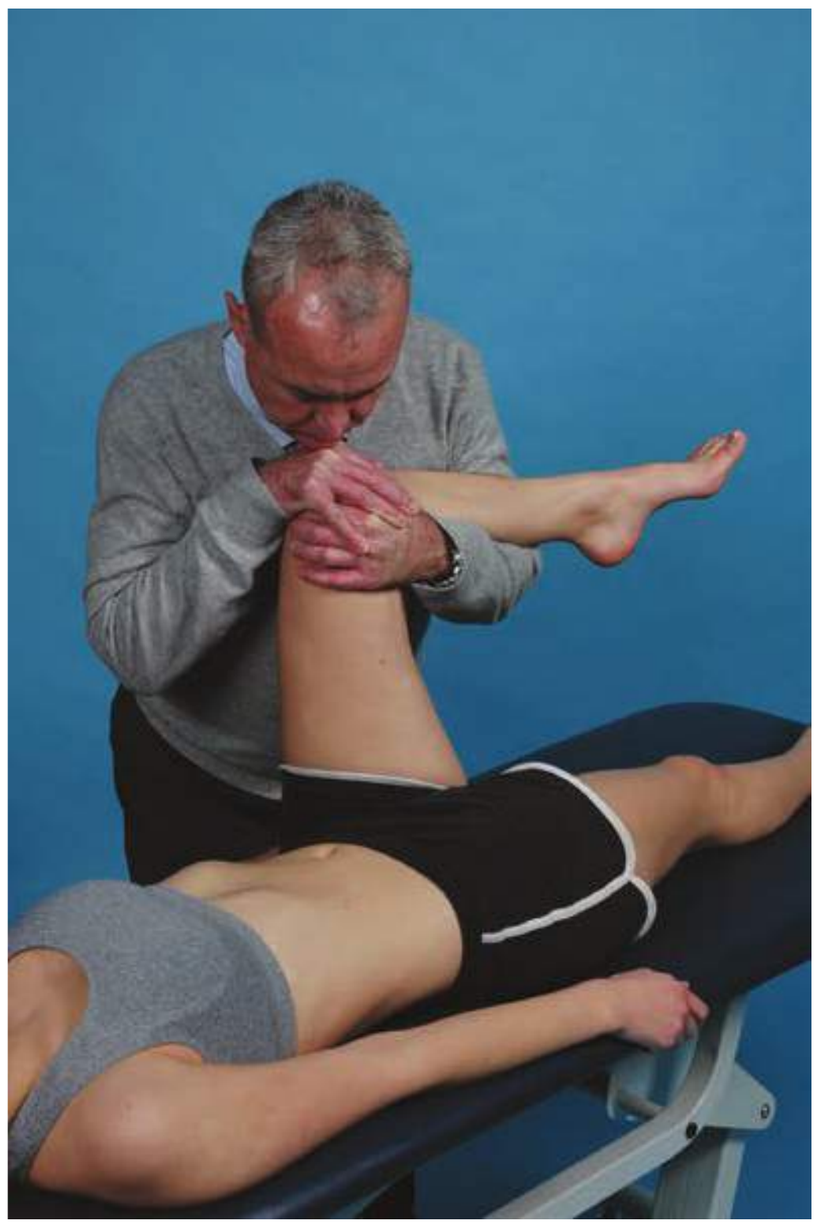

FIGURE 29-22 Posterior pelvic pain provocation test.

performed with the patient in supine. The clinician passively flexes the involved hip of the patient to 90 degrees, and a posteriorly directed force is applied through the longitudinal axis of the femur (Fig. 29-22). The test is considered positive for SIJ dysfunction if the patient reports a deep pain in the gluteal region during the test.

Mennell's Test. The patient is positioned in supine and the clinician positions the leg to be tested at 30 degrees of

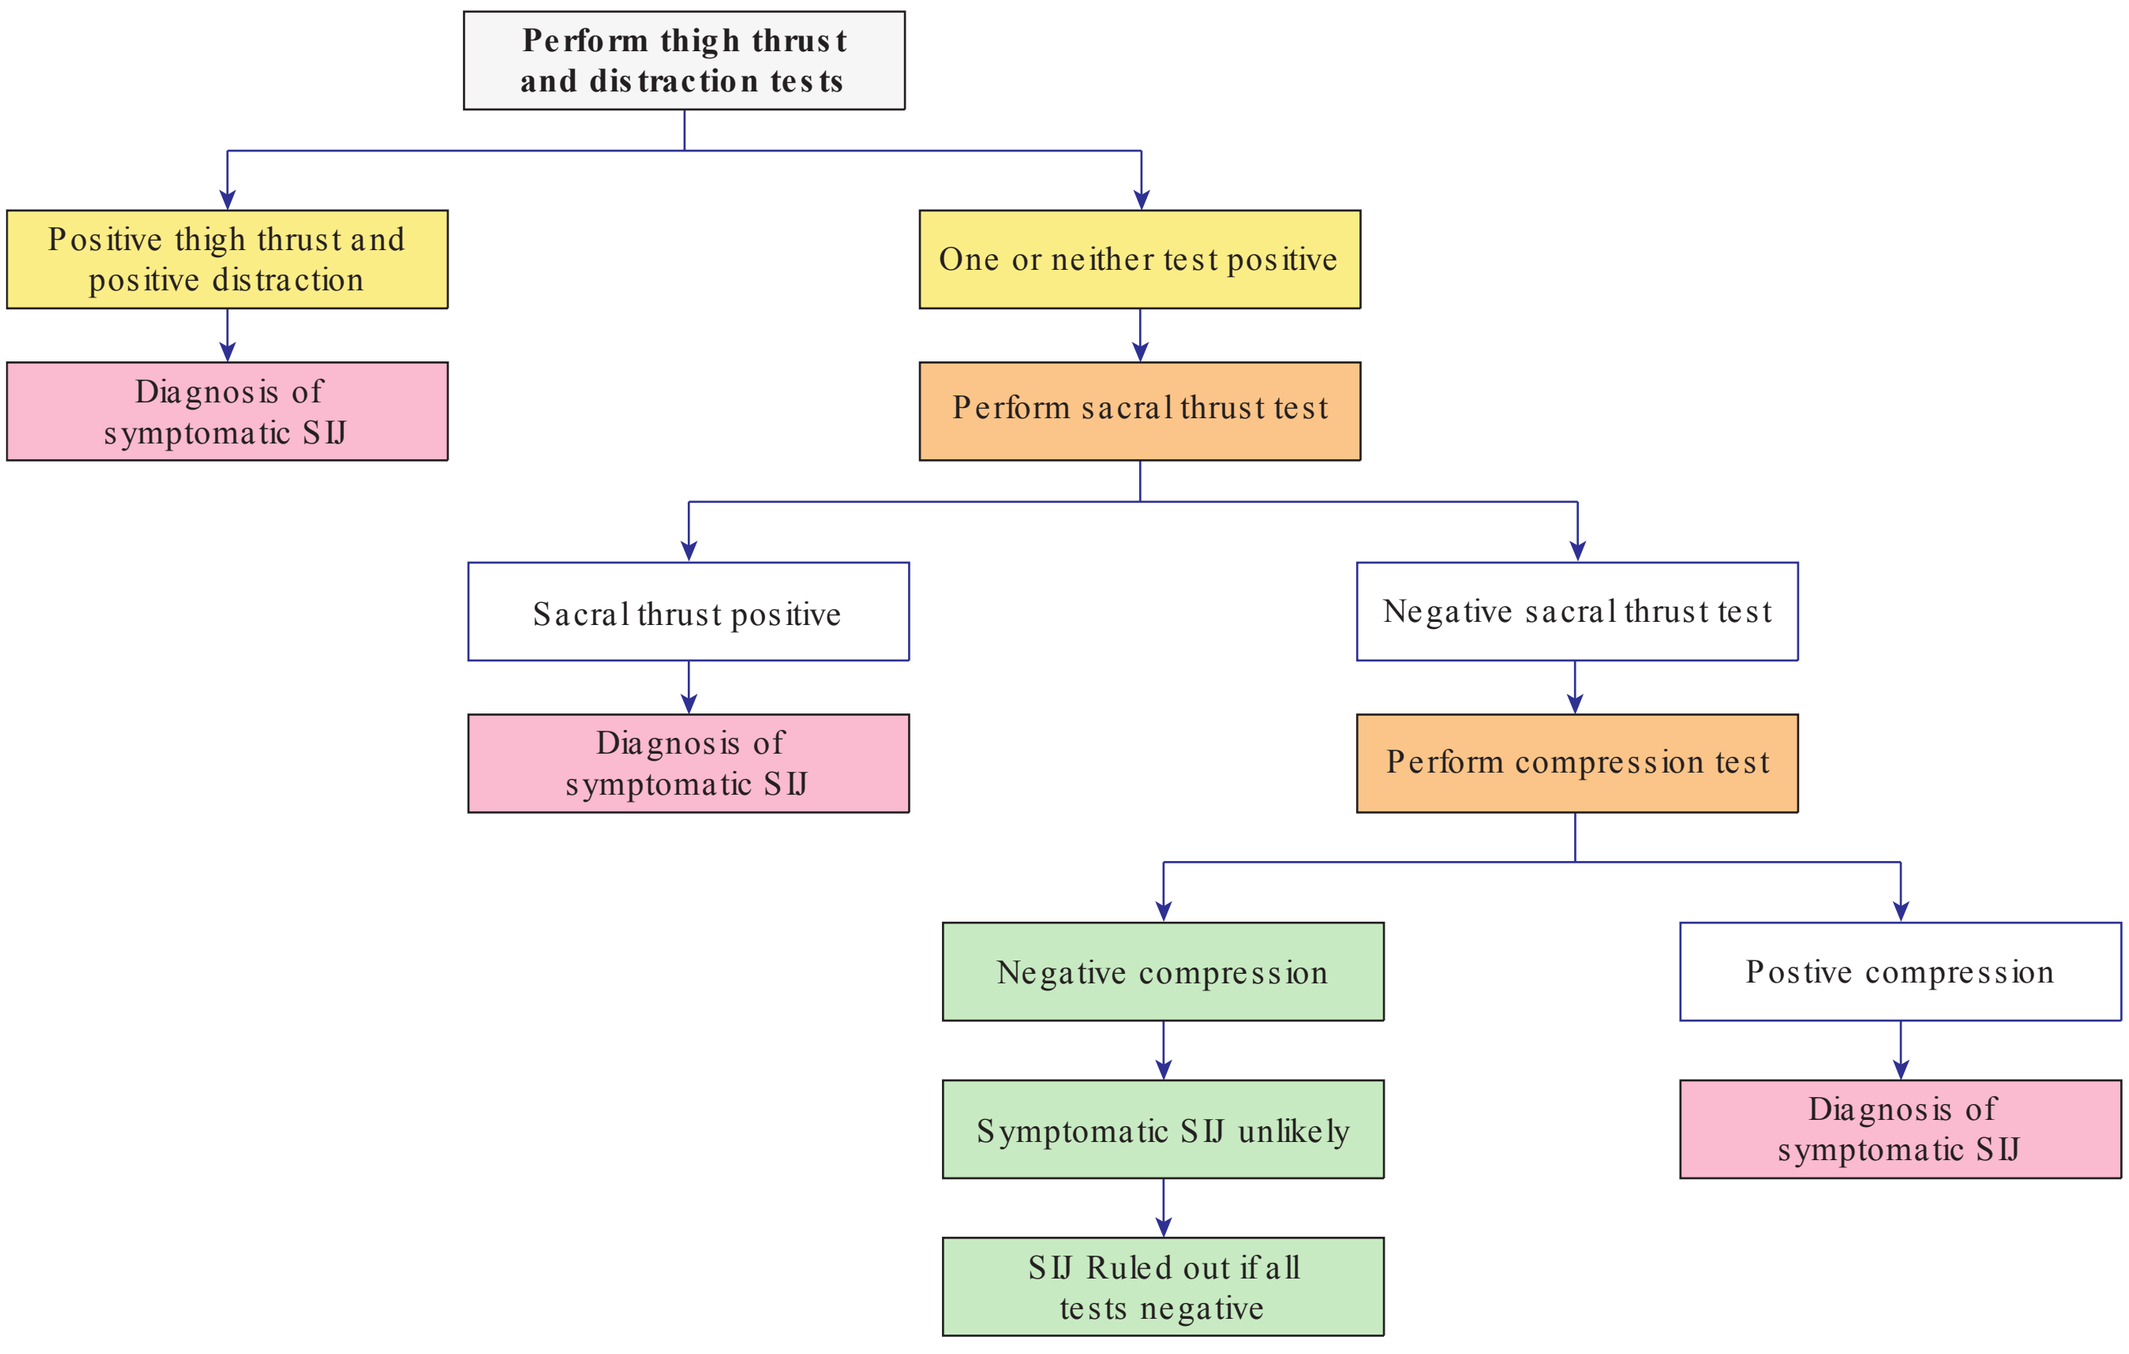

FIGURE 29-21 Diagnostic algorithm for the diagnosis.

FIGURE 29-23 Mennell's test.

abduction and some flexion of the hip joint (Fig. 29-23) and asks the patient to hold his or her leg in this position. The clinician pushes the lower leg into, and then away from, the pelvis in a sagittal motion (extension then flexion). A positive test is a reproduction of the patient's SIJ pain. Albert et al.[150] found this test to have a sensitivity of 54–70% and a specificity of 100%.

Resisted Hip Abduction. The patient is positioned in side lying, and the clinician positions the uppermost leg into extension and 50 degrees of abduction and asks the patient to hold his or her leg in this position. The clinician then applies a force medially (into the hip adduction) while the patient resists the force isometrically (Fig. 29-24). A positive test is a reproduction of SIJ pain in the superior aspect of the joint. Broadhurst and Bond[147] found the test to have a sensitivity of 87% and a specificity of 90%.

FIGURE 29-24 Resisted hip abduction.

Pubic Stress Tests. The patient is positioned supine and the clinician stands at the patient's side.[151] With the heel of one hand, the clinician palpates the superior aspect of the superior ramus of one pubic bone, and with the heel of the other hand, palpates the inferior aspect of the superior ramus of the opposite pubic bone. Fixing one pubic bone, the clinician applies a slow, steady, inferosuperior force to the other bone and, noting the quantity and end-feel of motion, as well as the reproduction of any symptoms, the clinician then switches hands and repeats the test so that both sides are stressed superiorly and inferiorly. Albert et al.[150] found this test to have a sensitivity of 81% and a specificity of 99% (LR+ 4.68; LR− 0.19). This test appears useful in the diagnosis of symphysiolysis.

CLINICAL PEARL

In some cases of trauma, or occasionally with child bearing, the pubis can become destabilized. This is a very severe and painful impairment, and one that is not easily missed. The pain is local to the pubic area, the patient is quite disabled with all movements, and weight-bearing postures are very painful. The impairment generally shows up on one-legged weight-bearing radiographs and often requires surgical intervention to stabilize the symphysis.

Fortin Finger Test. The patient completes a pain diagram and is then instructed to point to the region of pain using only one finger. The clinician reviews the area of pain and pain diagram for consistency and then asks the patient to repeat the procedure of pointing to his or her pain. A positive test for localization of SIJ pain has three criteria.

- The patient can localize the pain with one finger.
- The area pointed to is within 1 cm of, and immediately inferomedial to, the PSIS.
- The patient consistently points to the same area over at least two trials.

In a study by Fortin and Falco,[127] 16 subjects were chosen from 54 consecutive patients by using the Fortin finger test. All 16 patients subsequently had provocation-positive joint injections validating SIJ abnormalities (sensitivity of 100%). Another study by Dreyfuss et al.[55] found this test to have a sensitivity of 76% and a specificity of 47% (LR+ .09; LR− 1.3).

FABER or Patrick's Test. The FABER (flexion, abduction, external rotation) test is a screening test for hip (see Chapter 19), lumbar, or SIJ dysfunction, or an iliopsoas spasm.

The patient is positioned in supine, and resting symptoms are assessed. The clinician places the heel of the test leg over the opposite knee (placing the sole of the test leg foot against the medial aspect of the opposite thigh may be more comfortable for the patient with knee pathology). The hip joint is passively externally rotated and abducted while stabilizing the contralateral ASIS. The clinician asks the patient what affect the motion has on symptoms. The test is considered positive if the patient reports the reproduction of, or increase in, the anterior groin, posterior buttock, or lateral hip pain, which is consistent with the patient's presenting pain complaint. If no increase in pain is produced, the clinician then provides

a gentle downward pressure on both the knee of the painful side and the ASIS of the nonpainful side to determine the limit/end range of passive ROM and to again assess for pain provocation. An inclinometer is used to take a measurement. After being zeroed against a wall, the inclinometer is placed on the medial aspect of the tibia of the tested lower extremity, just distal to the medial tibial condyle. The ROM measurement is taken at the point of maximal passive resistance or at the point where the patient stopped the test secondary to pain.[152] A side to side comparison is made. Having the patient demonstrate where the pain is with this test may assist with the interpretation of this test. For SI pain, the chief complaint is typically posterior. In the various studies that have assessed the sensitivity and specificity of this test, there are a wide range of values which is likely reflective of the number of structures that are stressed during this test, and the variety of patients used in each study and the bias that results.[153–156]

Gaenslen's Test. The patient is positioned supine at the edge of the side of the bed with the painful leg resting very near to the end of the bed, and resting symptoms are assessed. The leg furthest from the edge of the bed (nontested leg) is flexed 90 degrees at the hip and held by the clinician using one hand. The clinician passively positions the upper leg (test leg) into hyperextension at the hip so that it hangs over the edge of the table (Fig. 29-25).[157] The clinician applies a further stretch to the test leg into hip extension and adduction up to six times while a flexion-based counter force is applied to the flexed leg. Pain with this maneuver is considered a positive test for an SIJ lesion, pubic symphysis instability, hip pathology, or an L4 nerve root lesion. The test also stresses the femoral nerve. This test demonstrates poor diagnostic value secondary to poor-to-fair specificity.[55] Overall, there is limited research pertaining to this test in order to make strong conclusions.

FIGURE 29-25 Gaenslen's test.

FIGURE 29-26 Yeoman's test.

Yeoman's Test. This test[158] is performed with the patient positioned prone. The clinician stabilizes the patient's sacrum with the palm of one hand. With the other hand, the clinician grasps the patient's distal thigh and extends the patient's hip (Fig. 29-26). At the end of the available motion, the hip is hyperextended so that the innominate is forced into anterior rotation. A positive test produces pain over the SIJ. Other structures that are stressed with this maneuver include the lumbar spine, the hip joint, and the iliopsoas muscle.

Seated Flexion Test (Piedallus Sign). The test is purported by osteopaths to help distinguish between an SI lesion and an iliosacral lesion when compared with the results of the standing flexion test.[5–7] The patient sits on a hard surface with the legs over the end of the table and feet supported.[8] In this position, the innominate motion is severely abbreviated, because sitting places the innominates near the end of their extension range. The test is performed as follows. Each PSIS is palpated with the thumb placed under it inferiorly (caudally). The patient then bends forward at the waist (Fig. 29-27). Provided there is no impairment in the SIJ or the lower lumbar spine, as the patient bends forward, both thumbs should move superiorly (cranially). If the joint is blocked, it moves superiorly further in relation to the other side.[113] However, like other palpatory tests, this examination has been shown to lack reliability, have poor sensitivity, and have low specificity and a low false-positive rate.[110,150,159] In contrast, Levangie[141] determine the sensitivity to be 9%, the specificity to be 93%, the positive predictive value to be 78%, and the negative predictive value to be 28%. Clearly there is a need for further study. A similar test, referred to as the sitting bend over test or sitting forward flexion test, is performed in the same manner

FIGURE 29-27 Seated flexion test (Piedallus sign).

except the patient is seated on a soft surface. However, this test has demonstrated poor sensitivity, poor reliability, and, therefore, has very poor diagnostic value.[141,159]

Long Sit Test. According to osteopath doctrine, the long sit test is used to indicate the direction of the rotation that the innominate has adopted and is used in conjunction with the standing flexion test. After noting the side of the impairment obtained from the standing flexion test, the clinician observes whether the medial malleolus on that side moves distally or proximally during the long sit test. Rotation about a coronal axis, whose resultant movement leads to an increase in the length of a limb, is defined as an extension. If it shortens the length of the limb, it is defined as flexion. T us, if the apparent shorter leg becomes longer during the test, the innominate on that side is purportedly held in a posteriorly rotated malposition, whereas if the apparent longer leg becomes shorter during the test, the innominate on that side is allegedly held in an anteriorly rotated malposition.

T e problems with this test involve the maneuver itself. To ask patients who are experiencing some degree of discomfort to raise themselves off the bed from a supine position into a long sit position without any twisting or use of the arms is unnecessarily painful. In addition, for the successful completion of the maneuver, the patient needs a minimum of 90 degrees of hip flexion and adequate hamstring length. Perhaps not surprisingly, the test has demonstrated poor reliability, questionable validity, and, therefore, may not yield useful results.[150,160]

Prone Knee Bending (Nachlas) Test. T is test was originally designed as a neurodynamic test for the femoral nerve. T e patient is positioned in prone and the clinician, while stabilizing the pelvis, flexes the knee so that the heel is brought toward the buttocks (Fig. 29-28). If pain is felt in the front of the thigh before full range is reached, the problem is in the rectus femoris muscle; if the pain is in the lumbar spine, the problem is in the lumbar spine (usually the L3 nerve root). If the problem is a hypomobile SIJ, the ipsilateral pelvic rim (palpated at the ASIS) will be felt to rotate forward.[161] Leboeuf[162] found this test to have a specificity of 83% and a sensitivity of 44% (LR+ 2.59; LR− 0.67). Riddle et al.[160] found this test to have an interrater reliability of 0.26.

FIGURE 29-28 Prone knee bending (Nachlas) test.

CLINICAL PEARL

Cibulka[163] et al. examined 219 patients with and without low back and SIJ mediated pain to examine the sensitivity, specificity, and positive and negative predictive values of four commonly used SIJ tests: the standing flexion test, sitting PSIS palpation, the long sitting test, and the prone knee flexion test. SIJ dysfunction was considered positive if at least three of the four tests were positive. The combination of these tests yielded a sensitivity of 0.82, a specificity of 0.88, a positive predictive value of 0.86, and a negative predictive value of 0.84. However, because the individual test results were not documented, no conclusion can be made about that isolated validity.

Leg-Length Tests. T ese are usually performed as part of the bony landmark examination. T eoretically, posterior rotation of the innominate on the sacrum results in a decrease in leg length, as does an anterior rotation of the innominate on the contralateral side.[164] Although not exact measurements of leg length, these tests can highlight any significant asymmetries.

Prone *T*est. Chiropractors assess leg length with the patient prone. T e comparative lengths of the legs are compared by observing the heels or the medial malleoli. If a discrepancy is noted, the knees are flexed to 90 degrees while maintaining neutral hip rotation, and the landmarks are reassessed to screen for a shortened tibia. T e patient is then positioned supine, and the leg lengths are reassessed using the same landmarks. Finally, the leg lengths are assessed using the long sit test. Functional leg-length inequality that is secondary to SI subluxation or dysfunction may reverse from the supine

to sitting position, whereas anatomic leg-length inequality or functional inequality secondary to dysfunction at other sites likely will not.[164]

Standing Leg-Length Test. The iliac crest palpation and book correction (ICPBC) method for assessing leg length is used in many clinics. The patient stands with the feet shoulder-width apart. The clinician palpates the iliac crests and compares the relative heights for asymmetry. The asymmetry identified is corrected using a book opened to the required number of pages and placed under the foot of the shorter leg. The iliac crest heights are reassessed. If the iliac crests are level, the thickness of the book correction is measured. One study with 34 healthy subjects found the ICPBC technique for measuring leg-length discrepancy to be highly reliable and moderately valid when there is no history of pelvic deformity, and the iliac crests can be readily palpated.[165]

Functional Leg Length. The patient stands with the feet shoulder-width apart. The clinician palpates the iliac crests, the ASISs, and the PSISs and compares the relative heights for asymmetry. The patient is then positioned with the subtalar joints in neutral, the toes pointing forward, and the knees fully extended. The same landmarks are reassessed. If the second position corrects any asymmetry found in the first position, the test is positive for a functional leg-length discrepancy and indicates that the leg is structurally normal but has abnormal joint mechanics.

Sign of the Buttock. The test for this syndrome is described here because its underlying pathologies occur in the lower quadrant The sign of the buttock is not a single sign, as the name would suggest, but rather a collection of signs indicating that a serious pathology is present posterior to the axis of flexion and extension in the hip (see Chapter 19). Among the causes of the syndrome are osteomyelitis, infectious sacroiliitis, fracture of the sacrum or pelvis, septic bursitis, ischiorectal abscess, gluteal hematoma, gluteal tumor, and rheumatic bursitis.

The patient lies supine, and the clinician performs a passive unilateral straight-leg raise. If a unilateral restriction is noted, the clinician flexes the knee and notes whether the hip flexion increases. If the restriction was caused by the lumbar spine or hamstrings, the hip flexion should increase. The sign of the buttock test is positive if the hip flexion does not increase when the knee is flexed. If the sign of the buttock is encountered, the patient must be immediately returned to his or her physician for further investigation.[166]

INTERVENTION STRATEGIES

Thus far, the success of interventions at this joint has been mixed, due in part to the poor reliability of many of the examinations used. The success of any intervention depends on the quality and accuracy of the examination and the subsequent evaluation. It follows that if the examination gives an inaccurate diagnosis, the intervention may have a mixed result. It is reasonable to assume that the SIJ is a source of pain for one of the two reasons.[167]

1. There is some support for the notion of an inflammatory condition within the joint either causing or associated with the pain.[168–170] Inflammatory processes such as those found in ankylosing spondylitis are known to affect the SIJ.
2. The joint is unstable through ligamentous laxity or weak musculature.[126,171,172]

Given that the chosen intervention for the SIJ, like the spine, depends largely on the philosophy or background that the clinician uses to establish the diagnosis. There appear to be three major schools of thought.[167]

1. Those who regard the SIJ as either irrelevant or rarely an issue in clinical practice.
2. Those who consider the clinical examination of the SIJ as either useless or of minimal utility.
3. Those who regard structural and biomechanical aspects of the SIJ as the key determinants of the problem of back pain.

Although the philosophies may differ, the principles behind the interventions for SIJ impairments should remain constant.

- A joint that has reduced motion (hypomobility) requires mobilizing techniques, muscle release techniques, and exercises that are designed to restore normal optimal alignment and controlled mobility.
- A joint that demonstrates excessive motion (hypermobility and/or instability) requires techniques and exercises that are designed to stabilize or balance forces around the hypermobile or unstable joint.[96] These include exercises to control joint motion and, on occasion, joint compression through the use of an external brace (SIJ belt).
- A joint that demonstrates signs and symptoms of excessive compression (due to intrinsic factors or extrinsic factors) requires techniques based on the cause of the compression. For example, joint compression caused by fibrosis benefits from the use of specific passive articular mobilization techniques whereas joint compression caused by over-activation of muscles benefits from techniques including muscle energy, trigger point therapy, and biofeedback.

The techniques and exercises used for the SIJ should always be based on the stage of healing and patient tolerance, and must take into account the influences that the lumbar spine and hip motions can have in this area.

Acute Phase

In the acute phase of rehabilitation for the SIJ, the intervention goals are to

- decrease pain, inflammation, and muscle spasm;
- increase weight-bearing tolerance, where appropriate;
- promote healing of tissues through sufficient stabilization;
- increase pain-free range of SIJ motion and surrounding structures;
- regain soft-tissue extensibility around the pelvic region;
- regain neuromuscular control; and
- allow progression to the functional stage.

For the most part, exercises are avoided in the acute phase because they tend to increase the symptoms. Pain relief may be accomplished initially by the use of cryotherapy, and electrical stimulation (TENS), gentle muscle setting exercises. T ermal modalities, especially ultrasound with its ability to penetrate deeply may be used after 48–72 hours. Ultrasound is the most common clinically used deep heating modality to promote tissue healing.[173–175]

Clinicians often correct leg-length discrepancies of greater than 0.5 inches, as such inequalities have been described as altering normal SIJ function.[176]

SIJ and pelvic stabilization orthoses have been employed to limit SIJ motion and improve proprioception (Fig. 29-29).[176–179] T ese measures are particularly indicated when the joint has been demonstrated to be inflamed by the anterior or posterior stress tests. Not much force from these belts (20–50 N) is necessary to afford relief to the patient.[177] T e position of the belt in terms of its height on the ilium should be experimented with to find the optimal position for pain relief. T e recommended position is just above the greater trochanter (Fig. 29-29). A bicycle inner tube can be used as a substitute SI belt, as this is the right width and has the correct degree of elasticity. T e following conditions appear to respond well to bracing:

1. Sacroiliitis.
2. SI hypermobility/instability (pre- and postpartum and microtraumatic).
3. Pubic instability (may afford some relief).

Once the pain and inflammation are under control, the intervention can progress toward the restoration of full strength, ROM, and normal posture. T e ROM exercises are initiated at the earliest opportunity. T ese are performed during the early stages in the pain-free ranges. Submaximal isometric exercises are then performed throughout the pain-free ranges. T ese exercises are progressed as the ROM and strength increase.

Aggressive manual therapy has a very limited place in the intervention of the acutely inflamed joint. In almost every case, the presence of a positive stress test contraindicates the use of passive mobilization or manipulation for that joint. However, mobilization or manipulation of the contralateral joint may reduce the stress on the painful and inflamed articulation. Gentle manual techniques such as myofascial release, grade I–II joint mobilizations, massage, gentle stretching, and muscle energy techniques should be attempted and continued if effective.

FIGURE 29-29 An SIJ orthosis.

Functional Phase

T e duration of this phase can vary tremendously and depends upon several factors.

- T e severity of the injury.
- T e healing capacity of the patient.
- How the condition was managed during the acute phase.
- T e level of patient involvement in their rehabilitation program.

T e goals of this phase are

- to reduce significantly or to resolve completely the patient's pain;
- to restore full and pain-free SIJ ROM;
- to integrate the lower kinetic chains into the rehabilitation;
- complete restoration of normal gait, where appropriate; and
- the restoration of pelvic and lower quadrant strength and neuromuscular control.

Intervention strategies should emphasize pelvic stabilization,[130] the elimination of trunk/lumbar/hip and lower extremity muscle imbalances, and the correction of gait abnormalities.[180] T e exercises used in the lumbopelvic stabilization exercise progression are described in detail in Chapter 28. During this stage, the patient learns to initiate and execute functional activities without pain and while dynamically stabilizing the SIJ in an automatic manner. Muscle imbalances around this joint complex are common. T e same principles apply here as elsewhere: stretch those muscles that are tight or adaptively shortened and strengthen those muscles that are found to be weak. T e muscles to be stretched around this joint complex are based on the clinical findings but usually include the erector spinae, the quadratus lumborum, the rectus femoris, the iliopsoas, the tensor fascia lata, the hip adductors, and the deep external rotators of the hip, especially the piriformis, and the gluteus maximus.[35,37] Postural correction and the correction of compensatory movements need to be addressed. Corrective exercises may be used to position the innominate bone in proper relation to the sacrum.

T e focus of the therapeutic exercises for this region is to augment the force-closure mechanism and to reduce any

stress that could prove detrimental to the SI complex. T e exercises prescribed must challenge and enhance muscle performance while minimizing loading of the SIJ to reduce the risk of injury exacerbation. Interindividual differences in injury status and/or training goals may allow for a continuum of required muscle stress and acceptable loading of the spine and SIJ.[181] Stabilization exercises and joint positioning can help the patient to (1) gain dynamic control of spine forces, (2) eliminate repetitive injury to the motion segments, (3) encourage healing of the injured segment, and (4) possibly alter the degenerative process.[182]

T e strengthening component of the exercises is aimed at improving the function of the muscles of the inner and outer groups. T e appropriate muscles must be isolated and then retrained to increase their strength and endurance, and to automatically recruit to support and protect the region.

A four-stage program has been designed to isolate and retrain the inner and outer muscle groups.[86,167]

Stage 1

- Levator ani. T e patient is first taught the location of the levator ani in supine. To strengthen the muscle, the patient is asked to shorten the distance between the coccyx and the pubic symphysis and to hold the contraction for 10 seconds (Fig. 29-30). When the muscle contracts properly, the transverse abdominis muscle can be felt to contract at a point 2 cm medial and inferior to the ASIS, there is no contraction of the buttocks, and by carefully palpating the sacral apex, the sacrum is felt to counternutate slightly as the levator ani contracts. T e exercise is repeated 10 times.
- Transversus abdominis/multif dus. T e abdominal drawing-in maneuver is one exercise known to result in preferential activation of the internal oblique and TrA.[85,183–185] To test for the isolation of the TrA, the patient is positioned prone, and a pressure biofeedback unit is placed underneath the abdomen (Fig. 29-31).[86,92] T e cuff is inflated to a base level of 70 mm Hg. T e patient is asked to draw the navel up and in toward the chest (abdominal hollowing). When the muscle contracts properly, an increase in tension can be felt at a point 2 cm medial and inferior to the ASIS. If a bulging is felt at this point, the internal oblique is contracting. T e multifidus is palpated simultaneously and should be felt to swell at a point just lateral to the spinous process.

FIGURE 29-30 Levator ani contraction.

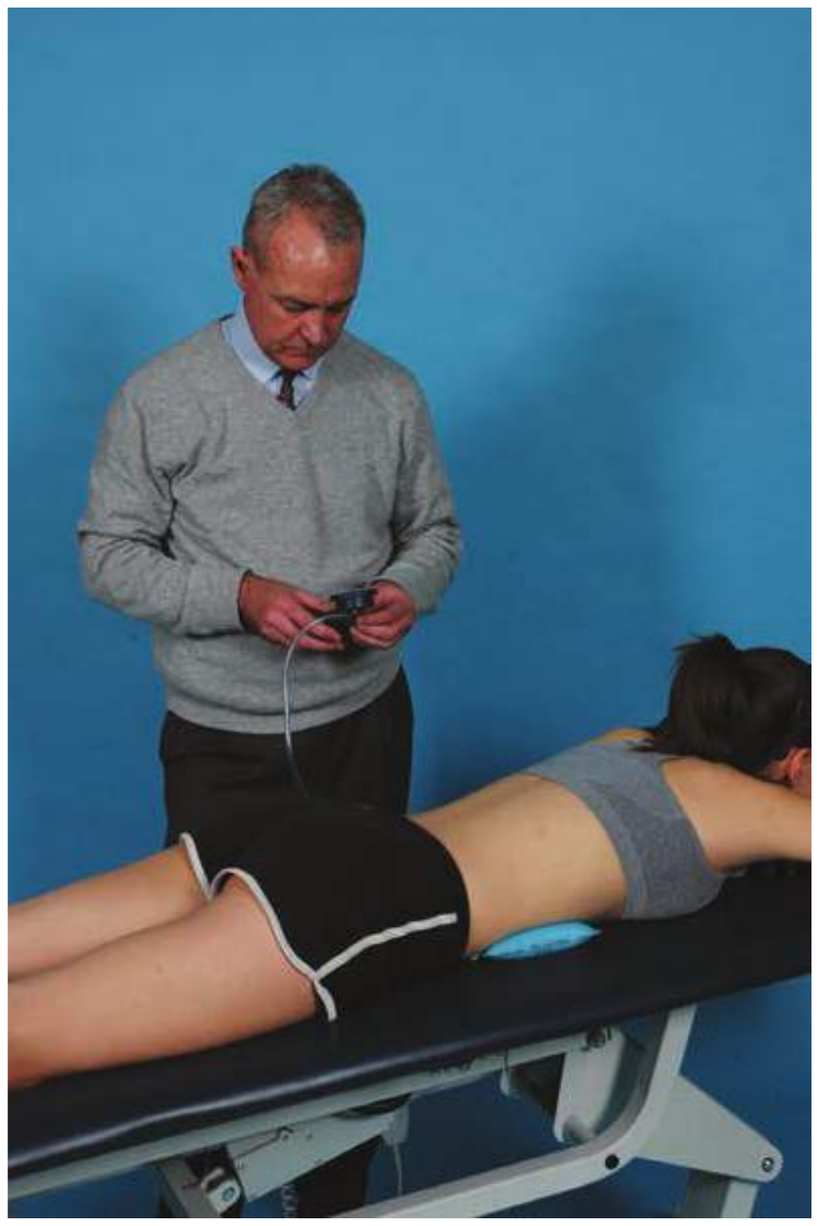

FIGURE 29-31 Transversus abdominis/multifidus.

Stage 2

T e stabilization program is progressed to the next stage with the introduction of lower or upper extremity motion, which changes the focus of the program from the inner muscle group to the outer muscle group.

In the supine position with the hips and the knees flexed, the patient is asked to isolate the inner muscle group while maintaining the lumbar spine in a neutral position. From this position, the patient is asked to let the knee slowly fall to one side (Fig. 29-32). Alternatively, the patient may extend the leg with the foot supported on the table.

T e next step in the progression involves asking the patient to extend this leg slowly while maintaining the hip and the knee flexed (with the foot lifted) without touching the table (Fig. 29-33). T is exercise initially is performed unilaterally and then is progressed to alternate leg extensions. T e same exercises may be performed sitting on a gym ball or lying supine on a long roll. By making the base unstable, the exercise becomes more dif cult without having to progress to the next stage.

Exercising on a gym ball requires core stability (inner muscle group control), coordination, and appropriate postural reflexes. While sitting on the ball, the patient is asked to contract the muscles of the inner muscle group. T is contraction is maintained while the patient moves forward and backward, and up and down on the ball. T e patient is instructed to incorporate the cocontraction of the inner muscle group into their activities of daily living.

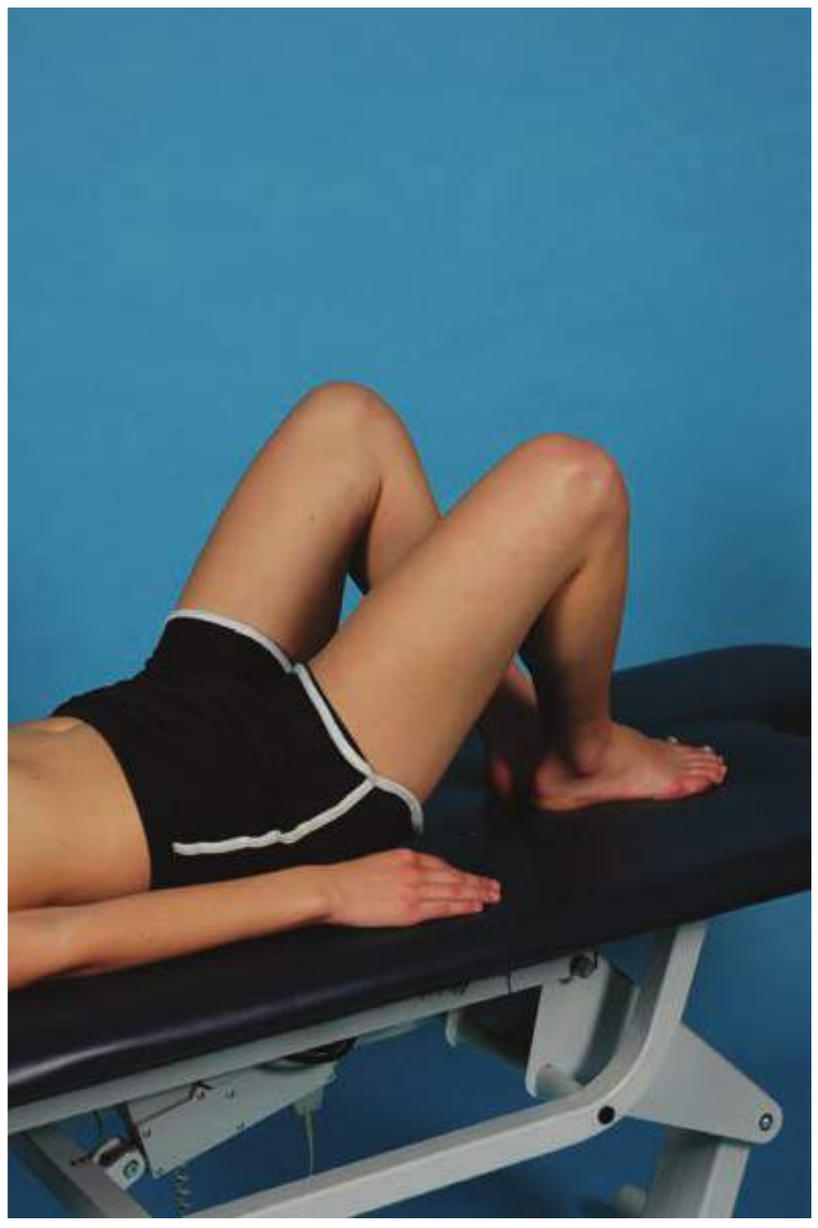

FIGURE 29-32 Knee fall-out.

If the individual muscles of the outer muscle group are weak or poorly recruited, the exercise program should include isolation and training at this time.

- Posterior oblique system. In the posterior oblique system, it is common to find the gluteus maximus both lengthened and weak.[84] Having the patient squeeze the buttocks together and sustain the contraction for 10 seconds isolates the gluteus maximus. A surface electromyography unit can provide a useful biofeedback system for this muscle. T e exercise is progressed by having the patient lie prone over a gym ball and asking him or her initially to recruit the inner muscle group and then to extend the hip while the knee is flexed. Lifting the extended thigh increases the degree of dif culty. Leg extension machines can help to strengthen the gluteus maximus. Initially, the patient exercises in the supine position with one or both feet on the foot plate. Functional training is introduced by having the patient practice going from sitting to standing with a stabilized trunk, using the gluteus maximus muscle primarily.
- Lateral system. In the lateral system, the posterior fibers of the gluteus medius are often weak, which can have a marked effect on walking and load transference through the hip joint.[104] Isolation of the gluteus medius is taught in the side-lying position with a pillow placed between the knees. T e exercise is progressed by asking the patient to lift the knee off the pillow and then to extend the knee while maintaining the correct position of the trunk and the hip. Resistance can be added using elastic tubing or a cuff weight.
- Anterior oblique system. Isolation of the anterior oblique system involves training the specific contraction of the external and internal oblique abdominals. When the external obliques contract bilaterally, the infrasternal angle narrows, whereas when the internal obliques contract bilaterally, the infrasternal angle widens. T e patient is taught to palpate the lateral costal margin and to widen and narrow the infrasternal angle through specific contraction of the oblique abdominals.

T e progression includes activation of the anterior and posterior oblique systems and differentiation of trunk from thigh motion. To begin, the patient is supine with the hips, and the knees flexed, both feet on the bed. T e patient is instructed to bridge and then to rotate the trunk and the pelvic girdle at the hip joints in the unsupported position while maintaining the lumbar joints in a neutral position.

Stage 3

Stage 3 exercises involve controlled motion of the "unstable region."[86] Because this stage is much more advanced, it is used only when required by an individual's work or sport. T e protocol includes concentric and eccentric work with variable resistance in all three planes.

Stage 4

Stage 4 of the protocol involves stabilization during high-speed motions. Very few people require stage 4 stabilization, particularly in view of the fact that high-speed exercise tends to reduce the stabilizing capability of the trunk muscles.[92]

In addition to the exercise program, the patient should be educated on the trunk and the lower extremity positions to avoid (those that produce an excessive or sustained sacral counternutation or a decrease in lumbar lordosis) and those to adopt (the positions that enhance sacral nutation and enhance the lumbar lordosis). For example, the patient should be advised to maintain an anterior pelvic tilt during sitting, either actively or passively with the use of a lumbar roll.

T e techniques to increase joint mobility and the techniques to increase soft-tissue extensibility are described under "T erapeutic Techniques".

As symptoms are controlled, therapy should be advanced to activity-specific stabilization exercises to facilitate a return to function at the patient's occupation, sport, or avocational activities.

FIGURE 29-33 Leg extension in supine.

Integration of Practice Patterns 4D and 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, Range of Motion Associated with Connective Tissue Dysfunction, and Localized Inflammation

Spondyloarthropathies

The spondyloarthropathies are a group of inflammatory arthritic conditions that share certain clinical and laboratory features (see Chapter 5).[186]

- Inflammatory arthritis, which manifests with pain associated with stiffness.
- The absence of a rheumatoid factor; hence the distinction of the group as "seronegative" spondyloarthropathies.
- The tendency for arthritis to be asymmetric and involve the lower extremities.
- Often, inflammation at the insertion of tendons into bone (enthesitis), accompanied by certain extraarticular features, including skin and mucous membrane impairments, bowel complaints, eye involvement, and aortic root dilation.
- The familial aggregation, which occurs within each condition and among the entities within the group.
- An association with HLA-B27, documented in the diseases included in this group.

Ankylosing Spondylitis

Ankylosing spondylitis (Bekhterev's or Marie–Strümpell disease) is a chronic rheumatoid disorder that is usually progressive, resulting in a full ankylosing of the SIJs.[186] Men generally have the most severe form affecting the spine, whereas, in women, the peripheral joints are more often affected.

The typical radiographic changes are seen primarily in the axial skeleton, especially in the SI, intervertebral, zygapophyseal, costovertebral, and costotransverse joints.[187] In addition, ankylosing spondylitis is one of the most common rheumatic disorders associated with radiologic abnormalities of the pubic symphysis, with pubic synchondrosis present in 20–25% of the patients.[188] In fact, changes in the symphysis can sometimes precede spine involvement.[188]

Tests to discriminate SIJ tenderness caused by ankylosing spondylitis from that caused by mechanical spine conditions have traditionally included a passive hip extension, A-P pressure applied to the sacrum, and the primary stress tests. However, these tests have been found to be poorly reproducible and inaccurate in making any distinction.[113]

Although radiologic evidence of sacroiliitis is accepted as being obligatory for the diagnosis of ankylosing spondylitis, the clinical signs (see Chapter 5) may predate radiologic abnormalities by months or even years.[186]

Groin Pain

Chronic pain in the groin region (see Chapter 19) is a difficult clinical problem to evaluate, and in many cases, the cause of the pain is poorly understood. The differential diagnosis of groin pain and tenderness includes adductor muscle strain, prostatitis, orchitis, inguinal hernia, urolithiasis, ankylosing spondylitis, Reiter's syndrome, hyperparathyroidism, metastasis, osteitis pubis, stress fracture, rheumatoid arthritis, tendonitis, degenerative joint disease of the hip, bursitis, stress fracture, conjoint tendon strains, inguinal ligament enthesopathy, and entrapment of the lateral cutaneous nerve of the thigh.[189–191]

Other nerve entrapment syndromes have been described as a possible cause of adductor region pain, with the anterior division of the obturator nerve in the thigh,[192] the ilioinguinal nerve, and the genitofemoral nerve having all been inculpated.[193]

Osteitis Pubis/Athletic Pubalgia

Since the original report of Gilmore's groin in 1980, various terms have been used to describe this entity, including a sports hernia, slap-shot gut, sportsman's hernia, hockey groin syndrome, and core muscle injury.[194] Many theories have been put forward concerning the etiology and progression of this condition, but the exact cause remains unclear, although there is an increasing awareness of an association between ROM and limiting hip disorders (femoral acetabular impingement) with this condition. This necessitates an evaluation of the hip joint to rule out an intra- or extraarticular hip pathology. A correct early diagnosis and management are important as this injury can lead to a high degree of disability.[195]

Osteitis pubis/athletic pubalgia, which is an activity-related lower abdominal and proximal adductor-related pain seen in athletes, is seen in individuals who participate in activities that create continual shearing forces at the pubic symphysis, as with unilateral leg support or acceleration–deceleration forces required during multidirectional activities. These include activities, such as running, race-walking, gymnastics, soccer, basketball, rugby, and tennis. The process could be the result of stress reaction, which might be associated with several biomechanical abnormalities. Overuse is the most likely etiology of the inflammation, and the process is usually self-limiting.[196]

CLINICAL PEARL

Osteitis pubis/athletic pubalgia has been likened to gracilis syndrome, an avulsion fatigue fracture involving the bony origin of the gracilis muscle at the pubic symphysis and occurring in relation to the directional pull of the gracilis.[197] However, osteitis pubis does not necessarily involve a fracture.

The pubic symphysis acts as a fulcrum for the anterior pelvis, and the structures implicated in the development of osteitis pubis/athletic pubalgia all have a close association with this fulcrum. From superficial to deep, the abdominal wall structures are the external oblique fascia and muscle, the internal oblique fascia and muscle, TrA muscle and fascia, and transversalis fascia.[194] Fibers from the rectus abdominis, conjoint tendon (formed by the internal oblique and TrA), and external oblique merge to form the pubic aponeurosis, which in turn is confluent with the abductor and gracilis origin (sometimes referred to as the abdominis/adductor aponeurosis).[194]

Osteitis pubis/athletic pubalgia usually appears during the third and fourth decades of life, occurring more commonly

in men.[198] Although the presentation can be variable, athletes typically complain of gradually increasing activity-related lower abdominal and proximal adductor-related pain.[194] By the time the individual seeks medical help, there is often pain with walking, which can be in one or several of many distributions: the lower rectus abdominis muscle perineal, testicular, suprapubic, inguinal, one or both groins and in the scrotum and perineum.[196] Symptoms of osteitis pubis have been described as "groin burning," with discomfort while climbing stairs, coughing, or sneezing.

During the physical examination, the potential sites of injury are palpated. The pubic tubercle and pubic symphysis are painful in up to 22% of patients.[199] Pain can often be elicited by having the patient squeeze a fist between the knees with resisted adductor contraction in flexion and extension. Alternatively, a resisted sit-up or crunch with palpation of the inferolateral edge of the distal rectus abdominis may recreate symptoms.[199] Valsalva maneuvers, such as coughing and sneezing can occasionally reproduce symptoms.[199] ROM in one or both hips may be decreased. An adductor muscle spasm might occur with limited abduction and a positive FABER test.[200] A soft-tissue mass with calcification and an audible or palpable click over the symphysis might be detected during daily activities.[196]

CLINICAL PEARL

In a cadaveric study by Birmingham et al.,[201] it was demonstrated that a simulated cam deformity increased motion at the pubic symphysis compared with the native non-cam state, supporting the hypothesis that motion-limiting femoral acetabular impingement may contribute to the development of athletic pubalgia in a subset of athletes.[194]

Rodriguez et al.[202] categorized osteitis pubis into four stages.

I. This stage is characterized by pain located in the unilateral kicking leg and a pain level that worsens after training.
II. This stage is characterized by bilateral inguinal pain and a pain level that worsens after training.
III. This stage is characterized by bilateral inguinal and lower abdominal muscle pain, and a pain level that worsens with kicking, sprinting, changing direction, long walks, and transitioning from sit to stand.
IV. This stage is characterized by bilateral inguinal, lower abdominal, and low back pain, and a pain level that worsens with defecation, sneezing, walking, and prevents the individual from performing ADLs.

It is also important to examine the position and mobility of the pelvic girdle. The normal position for the pelvic bowl is 45 degrees in the sagittal plane and 45 degrees in the coronal plane. Pubic motion is assessed by locating the pubic crest and then gently testing the mobility of each available direction. An altered positional relationship within the pelvic girdle is significant only if a mobility restriction of the SIJ or pubic symphysis, or both, is found. The inguinal ligament is usually very tender to palpation on the side of the impairment. Dysfunction of this articulation may be primary or secondary and, when present, is always treated first, because a loss of function or integrity of this joint disrupts the mechanics of the entire pelvic complex. The impairment pattern is determined by palpating the position of the pubic tubercles and correlating the findings with the side of the positive kinetic test, with the restricted side indicating the side of the impairment. It is common to find the pubic symphysis held in one of the four following positions:

1. Anteroinferior
2. Posterosuperior
3. Anterosuperior
4. Posteroinferior

These articular dysfunctions are treated using manual techniques (see "Therapeutic Techniques").

Plain film imaging may reveal degenerative changes such as subchondral cysts and osteophytes suggesting a prior injury.[195] MRI is 68% sensitive and 100% specific for rectus abdominis pathology compared with findings at surgery, and 86% sensitive and 89% specific for adductor pathology.[203]

Intervention for the inflammatory type of osteitis pubis is conservative and most athletes return to their respective sports within a few days to weeks.[204] The intervention includes plenty of rest from weight-bearing activities, a course of nonsteroidal antiinflammatory medicine, and physical therapy to gently mobilize, stretch, and strengthen the muscles of the groin.[205] Specifically, the rehabilitation should focus on core stabilization, postural retraining, and normalization of the dynamic relationship of the hip and pelvis muscles.[194] Patients should be able to swim for exercise. As the progression to return to sport begins, it may be helpful to avoid deep hip flexion, and low repetition, heavy weight strength training during this recovery period.[194]

A systematic review by Choi et al.[206] found that patients treated with a progressive rehabilitation program targeting pelvic girdle strengthening and stretching exercises along with a graduated running program were able to return to activity within 4 to 13 weeks. An intervention protocol for osteitis pubis is outlined in Box 29-1.

Corticosteroid and prolotherapy injections can be used in cases refractory to relative rest and rehabilitation.[206] Surgical intervention is reserved for recalcitrant cases and may include pubic symphysis debridement curettage, pubic symphysis fusion, or preperitoneal retropubic polypropylene mesh placement.[206]

Symphysis Pubic Dysfunction

Symphysis pubic dysfunction (SPD) describes the situation where the ligaments between the pubic symphysis become stretched and allow the bones to move with respect to each other (see Chapter 30). In severe cases, rupture of the symphysis may occur. This is more severe form is called diastasis symphysis pubis (DSP). SPD commonly occurs during pregnancy and should always be considered when examining patients in the postpartum period who are experiencing suprapubic, SI, or thigh pain. The associated ligamentous laxity during pregnancy is in response to the hormones progesterone and relaxin. Causes unrelated to pregnancy include

Box 29-1 Intervention Protocol for Osteitis Pubis

Phase I

1. Static adduction against a soccer ball placed between feet when lying supine. Each adduction is held for 30 seconds and is repeated 10 times.
2. Abdominal sit-ups performed both in straight direction and in oblique direction. Patient performs five sets to fatigue.
3. Combined abdominal sit-up and hip flexion (crunch). Patient starts from supine position and with a soccer/basketball placed between knees. Patient performs five sets to fatigue.
4. Balance training on wobble board for 5 minutes.
5. One-foot exercises on sliding board, with parallel feet as well as with a 90-degree angle between feet.

Five sets of 1-minute continuous work are performed with each leg, and in both positions.

Phase II (from third week)

1. Leg abduction and adduction exercises in side–lying position on side. Patient performs five series of 10 repetitions of each exercise.
2. Low-back extension exercises while in prone position over end of treatment table. Patient performs five series of 10 repetitions.
3. One-leg weight-pulling abduction–adduction in standing. Patient performs five series of 10 repetitions for each leg.
4. Abdominal sit-ups both in straightforward direction and in oblique direction. Patient performs five sets to fatigue.
5. One-leg coordination. Flexing and extending knee and swinging arms in same rhythm (cross-country skiing on one leg). Patient performs five sets of 10 repetitions for each leg.
6. Skating movements on sliding board. This is performed five times for 1-minute continuous work.

the possibility of a structural misalignment of the pelvis. This pelvic misalignment results in increased pressure on the pubic symphysis cartilage, with subsequent pain.

The symptoms of SPD and DSP vary from person to person. Subjectively the patient reports pain with any activity that involves lifting one leg at a time or parting the legs (e.g., lifting the leg to put on clothes, getting out of a car, turning over in bed, and walking up stairs). Objectively, the patient typically demonstrates an antalgic, waddling gait. Palpation reveals tenderness over the anterior pubic symphyseal area, and occasionally, clicking can be felt or heard. The ROM examination reveals limited hip movements due to pain, and there is an inability to perform unilateral standing. Radiological evaluation may occasionally be useful in confirming the diagnosis,[207] although the amount of symphyseal separation does not always correlate with severity of symptoms or the degree of disability.

Radiological evaluation may occasionally be useful in confirming the diagnosis.[185] Therefore, the intervention is based on the severity of symptoms rather than the degree of separation as measured by imaging studies.[207] Palpation reveals anterior pubic symphyseal tenderness. Occasional clicking can be felt or heard. The findings on the physical examination include positive SIJ stress tests (compression, distraction, and FABER tests). The range of hip movements will be limited by pain, and there is an inability to stand on one leg. Characteristic pain can often be evoked by bilateral pressure on the trochanters or by hip flexion with the legs in extension. However, such maneuvers may result in severe pain or muscle spasm and are not necessary for diagnosis.

In cases of DSP, there is likely an associated A-P compression (common) or a vertical shear (rare) fracture. Three types of DSP are described, indicating the severity of the injury.[208]

- Type 1 involves minor anterior damage, mild (less than 2.5 cm) pubic symphysis diastasis, and/or (vertical) pubic rami fractures.
- Type II has a wide diastasis of the symphysis pubis, disruption of the anterior SI ligament complex, and (hinging) of the iliac bone on the sacrum at the intact posterior SIJ.
- Type III designates total disruption of the SIJ, a diastasis of greater than 2.5 cm has been shown to indicate disruption of the anterior SIJ at least, but it is frequently associated with total SIJ disruption.

Although the symptoms can be dramatically severe, a conservative management approach, including bed rest in the lateral decubitus position, pelvic support with a brace or girdle, ambulation with an assistive device and a graded exercise progression, typically helps.[207] Patient education, which is extremely important in terms of providing advice on how to avoid stress to the area, should include the following suggestions:

- Use a pillow between the legs when sleeping, and keep the legs and hips parallel and as symmetrical as possible when moving or turning in bed and when standing and turning. Silk/satin sheets and night garments may make it easier to turn over in bed.
- Move slowly and without sudden movements.
- Sit down to get dressed, especially when putting on socks, shoes, or pants.
- If bending over to pick up objects is difficult, use specific devices such as reachers.

Swimming, with the exception of the breaststroke, and deep-water aerobics using floatation devices may help relieve pressure on the joint.

The symptoms of SPD typically resolve in approximately 6–8 weeks with no lasting sequela, although, in rare cases, residual pain occurs, requiring several months of physical therapy.[207] In severe cases surgical intervention may be utilized in cases of inadequate reduction, recurrent diastasis, or persistent symptoms.

Peripartum Posterior Pelvic Pain

More than 50% of women experience peripartum posterior pelvic pain (PPPP) or low back pain (LBP) during pregnancy with one-third of these women experiencing severe pain (see Chapter 30).[209–211] Hall et al.,[209] in a two-case report provided preliminary evidence suggesting that a combination of manual therapy (muscle energy techniques directed at identified pelvic and sacral positional faults) and therapeutic exercise (neuromuscular reeducation of the transverse abdominis and multifidus with isometric hip adduction and abduction in a semireclined position, and standing exercises to strengthen the posterior oblique system [gluteus maximus and contralateral latissimus dorsi]) may be an effective intervention for peripartum patients reporting posterior pelvic pain.[209]

Coccydynia

Coccydynia, sometime referred to as coccygodynia, is a painful and potentially debilitating condition that may be related to trauma, pregnancy (see Chapter 30), obesity, or other unidentifiable causes.[212] Women are four times more likely to have symptoms consistent with coccydynia, and individuals with an increased body mass index are three times more likely to develop this painful condition.[213]

CLINICAL PEARL

Coccydynia is associated with posterior sacrococcygeal subluxation from repeated or prolonged sitting loads.[214]

T ere are a number of ligaments around this area which can be injured.

- Anterior (ventral).
  - Lateral sacrococcygeal.
  - Anterior (ventral) ligament of the coccyx (caudal extension of the anterior longitudinal ligament).
- Posterior (dorsal).
  - Superficial posterior (dorsal) sacrococcygeal (caudal extension of the ligamentum flavum).
  - Deep posterior (dorsal) sacrococcygeal (caudal extension of the posterior longitudinal ligament).
  - Intercornual ligament.

T e dominant muscle in this area is the levator ani, which has connections with the

- iliococcygeal ligament;
- pubococcygeal ligament.

Coccydynia tends to occur when the coccyx becomes stuck into flexion with an accompanying deviation. Diagnosis of this condition is based on clinical presentation and, often, static-view radiological imaging to identify displacement of the coccyx.[16] On occasion, dynamic imaging can also be performed to assess abnormal mobility by comparing the position of the coccyx in standing versus a seated position, although there is no imaging gold standard for the diagnosis.[16]

CLINICAL PEARL

Instability of the coccyx has been defined as a flexion movement that exceeds 25 degrees or extension movement that exceeds 20 degrees,[16] although a dynamic magnetic resonance imaging study in 2007 demonstrated excursion of up to 31 degrees of flexion in asymptomatic individuals.[215]

Little research has been done in the conservative management of coccydynia. A typical intervention includes nonsteroidal antiinflammatory drugs, manual therapy, and local cortisone injections.[216,217]

Given the intrarectal nature of this examination, it is critical that the procedure is carefully explained to the patient, and verbal consent is obtained prior to performing the examination. T e manual therapy component involves grasping the coccyx with the thumb and index finger of one hand after inserting the index finger into the anal canal while stabilizing the pelvis with the other hand. Once in position, the clinician assesses the degree of movement in the anterior-to-posterior direction (Fig. 29-34A). If the mobility is felt to be restricted, the coccyx can either be distracted (Fig. 29-34B), or mobilized in a medial to lateral (Fig. 29-34C) direction, or an anterior, or posterior (Fig 29-34D) direction.

Practice Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, Range of Motion Associated with Fracture

Sacral Stress Fracture

Repetitive loading on the body can lead to the development of stress fractures. Stress fractures have been described as a cause of back pain, especially fractures of the pelvis and pars interarticularis of the sacrum.[218] Back and buttock pain caused by sacral stress fractures are less common but may occur in athletes and in the elderly.[219] Fractures in the latter group have been reported both with and without trauma.

T e cause of sacral stress fractures is controversial. T ese fractures are believed to result from stress concentrations of vertical body forces, which are dissipated from the spine to the sacrum and the sacral alae and then onto the iliac wings.[220] In addition to abnormal stresses on the normal bone, normal stress on an abnormal bone can produce these fractures, especially in the elderly. Patients who sustain such insufficiency fractures may have predisposing factors, including idiopathic osteoporosis, irradiation-induced osteoporosis, steroid-induced osteoporosis, or osteoporosis associated with malignancy.[218] Another cause cited for sacral fractures is a progressive insufficiency of the supporting muscles.[221] T ese fatigue fractures may result from the transfer of loading forces directly to the bone, without absorption of some energy by the muscles. Other reported causes of sacral stress fractures are differences in physical demands, environmental and genetic influences, training methods, footwear, and intensity of training.[221] Atwell and Jackson[222] suggested that leg-length inequality may increase the stress on one side of the sacrum, but this has not been proven by biomechanical analysis.[218]

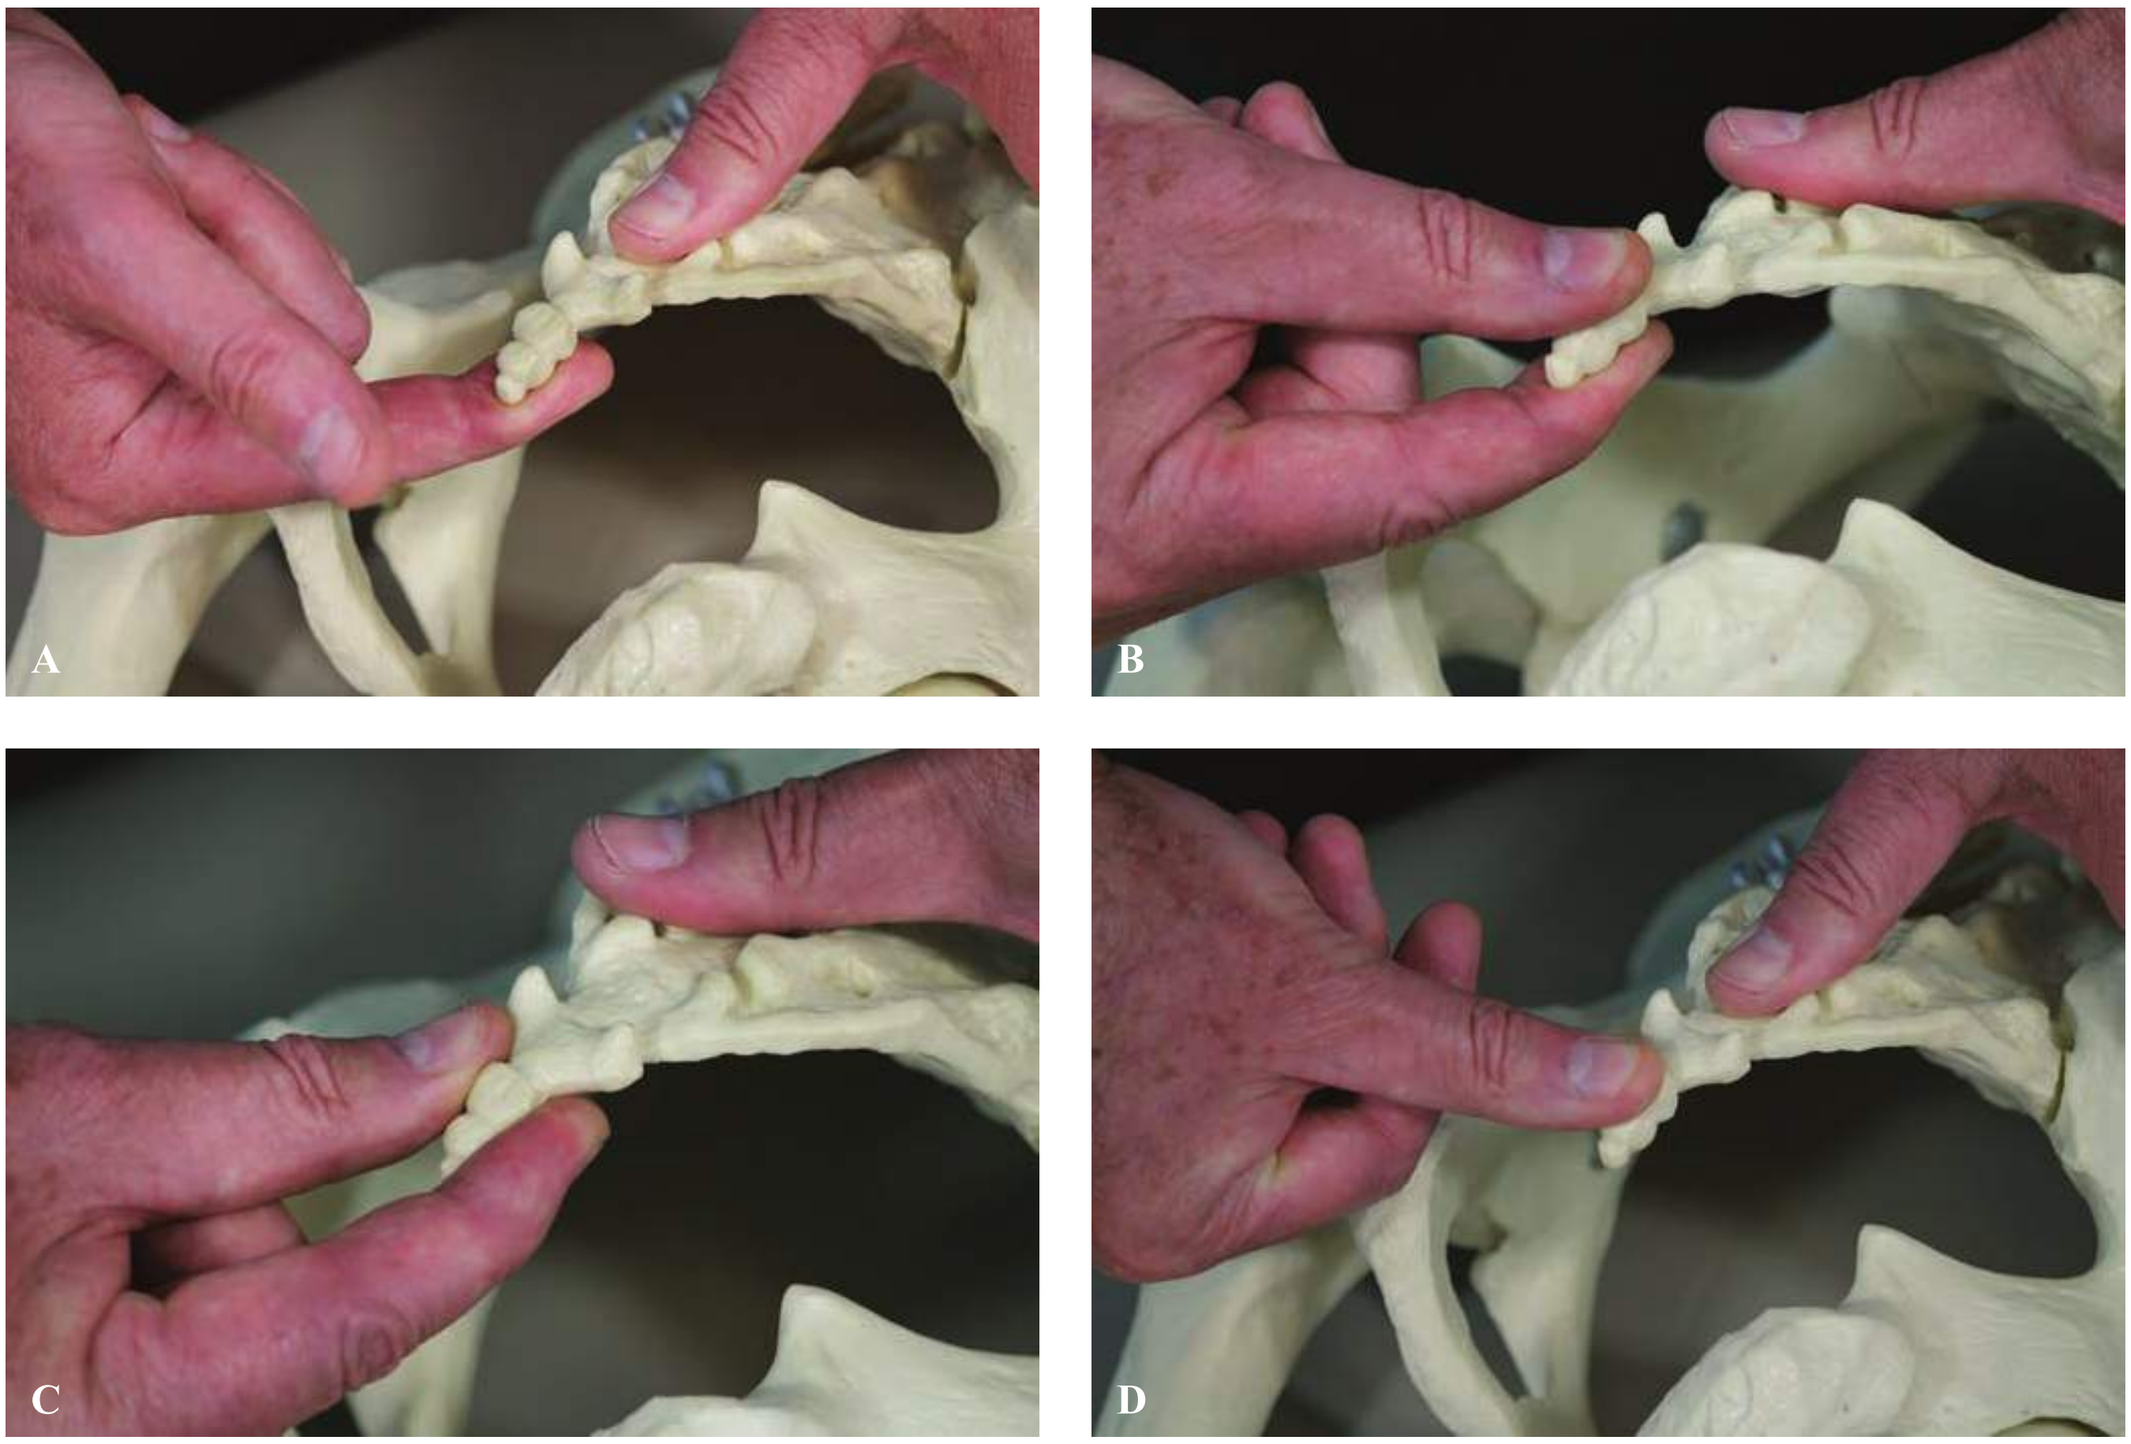

FIGURE 29-34 A. Mobility testing of the coccyx. Mobilization of the coccyx into (B) Distraction, (C) Medially-Laterally, and (D) Posteriorly.

Patients with sacral stress fractures typically present with low back pain and sacral pain that may radiate into the buttocks. However, pain may be referred to the groin and, occasionally, down the leg.[222] In the case of an athlete, the history may reveal a recent history of a stress fracture in the same area, or a rapid increase in training intensity prior to the onset of symptoms.[132] Insuf ciency fractures of the sacrum in nonathletes have been reported to mimic disk disease, spinal stenosis, and tumors.[223] Irritation of the cauda equina or the sacral nerve roots may explain the wide variety of symptoms seen in patients with sacral stress fractures.[218,224]

A physical examination may not provide reliable signs initially because many of these patients have diffuse low back, sacral, and buttock pain. However, most patients will have localized tenderness over the sacrum and SIJ.[218–220,222,223,224] Tenderness in the upper gluteal areas tends to be coexistent with sacral stress fractures, and tenderness in this region may contribute to the impression that the origin of the pain is centered in the more proximal lumbar spine.[218] Most patients are neurologically intact, with no signs of nerve root irritation. T e Patrick's, or the FABER test may or may not be positive, so it cannot be depended on in making a diagnosis.[218]

T e most sensitive method of evaluating the sacrum for occult stress fractures and other bone lesions is a bone scan using three-phase scintigraphy.[225] T is bone imaging technique can help detect stress fractures as early as several days after the fracture occurs. In contrast, plain radiographs of the lumbosacral spine and the pelvis, although useful to rule out other causes of back pain are not helpful in diagnosing sacral stress fractures.[219]

Patients with sacral stress fractures recover quickly with rest. Most patients are able to return to their normal activity levels in 4–6 weeks with no long-term sequelae.[218] Antiinflammatory agents and analgesics may be used as adjunctive treatment for patient comfort. Cycling or running in a pool may be used until weight-bearing activities are tolerated.

Pelvic Stress Fracture

Pelvic stress fractures are rare (1.6–7.1% of all stress fractures) and can be dif cult to detect, requiring a high degree of suspicion.[226] Pubic rami fractures are more common in women.[227] Plain radiographs are the first step in imaging, but magnetic resonance imaging is the imaging modality of choice for definitive diagnosis.[227]

THERAPEUTIC TECHNIQUES

Normally, pelvic impairments are presented as isolated entities when, in fact, clinically, they tend to occur in combination. It is essential that the impairments, functional limitations, and disability found during the examination guide the intervention.

FIGURE 29-35 Method to restore posterior rotation of the right innominate.

To Restore Posterior Rotation of the Right Innominate

The patient is in the prone lying position, with the right hip and the leg over the edge of the table. The clinician stands at the patient's right side. The patient's right foot is placed between the clinician's legs and held there. While monitoring the sacral sulcus with the index finger of the left hand, the clinician moves the patient's right leg to the barrier (Fig. 29-35). The patient is asked to push the right foot toward the foot of the table gently. This movement is resisted by the clinician's legs, and after 3–5 seconds, the patient is told to relax. Once again, when full relaxation has occurred, the slack is taken up, and the patient's right leg is moved in the direction of hip flexion until the monitoring finger indicates the new barrier has been reached. This mobilization is repeated three times and followed by a reexamination.

FIGURE 29-36 Method to restore anterior rotation of the left innominate.

To Restore Anterior Rotation of the Left Innominate

The patient is in the prone lying position, with the clinician standing on the patient's side. With the left hand, the clinician supports the anterior aspect of the patient's left thigh, at a point just above the knee. The clinician places the heel of his or her right hand over the patient's left PIIS. Extending the left hip until motion at the lumbosacral junction is perceived (Fig. 29-36), the clinician localizes the motion barrier. The patient is instructed to flex the left hip against the clinician's resistance. This isometric contraction is held up to 5 seconds, following which the patient is instructed to relax completely. The new barrier to anterior rotation is achieved by further extension of the hip. The mobilization is repeated three times and followed by a reexamination of function.

CASE STUDY

Left-Sided Low Back and Buttock Pain

HISTORY

A 47-year-old man presented at the clinic, with left-sided low back and buttock pain that had developed while he was at work 2 weeks previously. When describing the mechanism of injury, the patient reported feeling something "pop" in his low back during a lifting maneuver that involved bending forward and twisting to the right. The pain was now localized to an area slightly inferior to the left PSIS, which he reported as being very tender to the touch. The pain was aggravated with forward bending and turning at the waist to the left in the sitting position. The patient reported sleeping well, if he remained prone, and there were no complaints of paresthesias or anesthesias. The patient denied any neurologic symptoms related to cauda equina or spinal cord involvement. He was in otherwise good health.

Questions

1. Given a distinct mechanism of injury, what type of structure(s) could be at fault with complaints of left-sided low back and buttock pain?
2. What does the region of localized tenderness tell the clinician?

3. Why do you think the patient is sleeping well in the prone position?
4. What is your working hypothesis at this stage? List the various diagnoses that could manifest with low back and buttock pain, and the tests you would use to rule out each one.
5. Does this presentation/history warrant a scan? Why or why not?

CASE STUDY

PUBic Pa in

HISTORY

A 44-year-old man came to the clinic complaining of worsening abdominal and midline pelvic pain. The pain had developed gradually, and there was no report of recent direct trauma or acute injury. The pain was aggravated with forced flexion at the waist and the Valsalva maneuver, but the patient reported no pain at rest. The pain, described as a sharp, "stabbing" sensation, remained fairly localized to his upper pelvis and lower abdominal area.

The patient had no history of abdominal or genitourinary diseases or surgeries, and he had not experienced similar symptoms in the past. A review of systems was unremarkable. He denied dysuria, hematuria, diarrhea, constipation, fever, chills, or weight change.[185]

The patient frequently participated in physical activity and played soccer, averaging four games per week, an increase from his usual level of commitment. An inguinal hernia had been ruled out by his physician.

Questions

1. What structure(s) could be at fault when abdominal and midline pelvic pain is the major complaint?
2. What is the significance of the Valsalva maneuver?
3. Why are the questions with regard to dysuria, hematuria, diarrhea, constipation, fever, chills, or weight change pertinent?
4. What does no pain at rest suggest?
5. What is your working hypothesis at this stage? List the various diagnoses that could manifest with this pain and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?

SECTION VI

SPECIAL CONSIDERATIONS

CHAPTER 30 Special Populations

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Discuss the physical therapy role with a variety of orthopaedic subtypes and the challenges each present.
2. Describe the various pathologies for these populations in terms of the presentation and the role that physical therapy plays.
3. Outline the differences between a congenital condition and an acquired condition.
4. Describe the normal aging process as it relates to orthopaedics.
5. Outline the various theories of aging.
6. Describe the common pathological conditions and functional limitations associated with the geriatric population.
7. Describe some of the conditions that can affect women's health.
8. Describe the physiologic changes that occur during pregnancy within the various bodily systems.
9. Describe the physical therapy interventions for pregnancy-related dysfunctions.
10. Describe the complications related to breast-cancer–related lymphedema.
11. Describe the common pathological conditions associated with a number of popular sports including swimming, rowing, throwing, tennis, and running.

OVERVIEW

There are a number of population subtypes that require special consideration in terms of the orthopaedic examination and intervention. These include pediatrics and geriatrics, and the whole spectrum of women's health, in addition to the problems associated with a number of sports.

The Pediatric Athlete

The term pediatric refers to the 0- to 21-year age range, during which an individual undergoes many changes while aging, evolving, and maturing. During the preschool years, physical growth, neurologic growth, and maturation are quite rapid and apparent, with new skills being acquired at a quick pace.[1] This process continues throughout the middle years (ages 6–11) at a somewhat slower pace. As a child enters puberty, the rapid development of physical and sexual characteristics become more apparent and is accompanied by important psychosocial development. It is important to remember that chronologic age does not necessarily correlate well with many physiologic and somatic changes.

CLINICAL PEARL

Atypical adult has a smaller surface area-to-mass ratio and a lower metabolic rate than a child. These discrepancies result in a greater transfer of heat and a greater challenge to the thermoregulatory system, respectively, in the pediatric population.

The major characteristics of somatic and skeletal growth and maturation during adolescence are outlined in Table 30-1. In addition, the following differences exist between the adult and the pediatric patient[2]:

- Cardiovascular system. The pediatric heart is smaller than that of the mature adult, resulting in a smaller capacity as a reservoir for blood, and thus a lower stroke volume at all levels of exercise, which is compensated for by an increased heart rate. As with the adult patient, systolic blood pressure (BP) rises during exercise in the pediatric patient, but the elevation is less. Finally, the thoracic cavity is obviously smaller in the younger child than that of the mature adult, resulting in the pediatric patient demonstrating a smaller vital capacity than the adult and an elevated resting respiration rate.[3] The red blood cell count for young boys and girls are similar in comparable abilities to carry oxygen to exercising organs. After menarche, however, females demonstrate lower blood volume and fewer red blood cells with a resultant decreased oxygen carrying capacity and a lower mean

TABLE 30-1 Somatic and Skeletal Growth and Maturation During Adolescence

Characteristic	Description
Weight	In males, the average weight gain during its peak is approximately 9 kg per year with a range of 6–12.5 kg per year. The peaks of growth spurts in height, weight, and muscle occur at the same time In females the average weight gain during its peak is approximately 8 kg per year with a range of 5.5–10.5 kg per year. The peaks of growth spurts in height, weight, and muscle occur in sequence in that order
Height	In general, linear growth first occurs in the lower extremities, followed by the torso and then the upper extremities Males typically reach their peak height velocity (PHV) by 14 years. The growth of the shoulders in males is the most noticeable change Females typically reach their PHVby 12 years. The growth of the hip and pelvis in females are the most notable changes
Body composition	In general, both males and females tend to increase both fat mass as well as fat-free mass from the early to middle adolescent years. However, while males may show a transient decrease in fat accumulation in the extremities during PHV, females continue to gain fat through late adolescence. The pattern of growth of fat-free mass is similar to that noted for growth in height and weight
Flexibility	As skeletal growth precedes that of musculotendinous growth during the early to middle adolescence, there is a relative decrease in musculotendinous flexibility in some adolescents, especially males. Decreased flexibility is particularly noticeable in the hamstrings and ankle dorsiflexors
Muscle growth and strength	Although muscle growth and strength is seen in both males and females, it is relatively more pronounced in males compared with females due to androgens
Bone mass	The female skeleton generally grows and fully matures (i.e., growth plate fusion) before the male skeleton. The largest percentage of lifetime acquisition of bone mineral density occurs during the second decade of life. Peak bone mass during adolescence is determined by genetic influences, exercise, calcium intake, and hormonal status

Data from Greydanus DE, Pratt HD. Adolescent growth and development, and sport participation. In: Patel DR, Greydanus DE, Baker RJ, eds. Pediatric Practice: Sports Medicine. New York, NY: McGraw-Hill; 2009:15–25.

BP.[4] T ese differences result in the following responses to exercise in the pediatric patient:

- Until 12 years, absolute maximal oxygen uptake (VO_{2max}) values increase at the same rate in both genders, although boys have higher values as early as 5 years. VO_{2max} increases concomitantly with growth until 18 years in boys and 14 years in girls.
- T e pattern of relative magnitudes of cardiovascular and ventilatory responses to progressive and sustained dynamic exercise appears to be qualitatively similar between adults and children.
- Children rely more on oxidative rather than anaerobic metabolism compared to adults.
- Children demonstrate greater energy expenditure during weight-bearing activities such as running and walking compared to adults.

Musculoskeletal system. During infancy, early childhood, and preadolescents, muscle accounts for about 25% of body weight with the total number of muscle fibers established prior to birth or early in infancy. Postnatal changes in the distribution of type I and type II muscle fibers (see Chapter 1) are relatively complete by the end of the first year of life, with the muscle fiber size and mass increasing linearly from infancy to puberty. T roughout childhood until puberty, muscle strength and muscle endurance increase linearly with chronological age in boys and girls with muscle mass (absolute and relative) approximately 10% greater in boys than girls. Of interest is that training induced strength gains occur equally in both sexes during childhood without evidence of muscle hypertrophy until puberty. During this time, children possess muscle fiber numbers, types, and distribution similar to that of adults. During puberty, there is a rapid acceleration in muscle fiber size and muscle mass, especially in boys, with muscle mass increasing more than 30% per year. As would be expected, this increase in muscle mass results in a rapid increase in muscle strength in both sexes but there is a marked difference in strength levels between boys and girls. In boys, muscle mass and body weight and weight peak before muscle strength, whereas in girls, strength peaks before body weight. T e increase in muscle hypertrophy is a result of increased androgens. In addition, agility, motor coordination, power, and speed also show improvement during puberty.

In addition, growth cartilage is present at the epiphyseal plate during puberty, the joint surface (articular cartilage), and the apophysis. T e epiphyseal plate or growth plate is divided into zones differentiated from one another via structure and function (see Chapter 1). Growing bone is the weak musculoskeletal link in the young athlete. Similar physical demands that can result in muscle strain or ligament sprain in the skeletally mature patient may result in an epiphyseal plate injury in a young patient. Two factors that impact epiphyseal

plate injury are (1) the ability of the growth plate to resist failure and (2) the forces applied to the bone or the stresses induced in the growth plate. T e majority of epiphyseal fractures are due to high-velocity injuries.

A certain amount of load is necessary for normal bone growth and remodeling. In most long bones, epiphysis is at least partially ossified at an early age. However, in certain areas of the body (e.g., ischial tuberosity, iliac crest, the base of the fifth metatarsal), the epiphysis may not become ossified until the near end of the final growth spurt. Most of the bone mineral density (BMD) is acquired during the adolescent years, and bone mass may fail to accrue optimally because of dieting and weight loss. Because the strength development of bones lags behind that of ligaments and tendons, there is an increased risk of tendon or bone avulsion at the apophyseal insertion compared to a ligament injury.

CLINICAL PEARL

Orthopaedic injuries commonly seen in the pediatric population include Osgood–Schlatter disease, spondylolysis, stress fractures, Little League elbow, and growth plate disorders.

Examination of the Pediatric Patient

In addition to the areas typically covered in the orthopaedic examination outlined in Chapter 4, a number of additional factors must be considered in the pediatric population. For example, when taking the history of a pediatric patient, the clinician should pay particular attention to the following[2]:

- Current life circumstances. T e pediatric patient's current health, attitudes and values of the child's immediate family, and acculturation of the patient.
- Gender. Females and males develop differently, particularly during adolescence (Table 30-2).
- Health history. Health and nutrition history, repeated hospitalizations, and so on.
- Developmental history. T e pediatric patient's past rate of achievement of developmental milestones, events that might have had profound effects on the patient either physically or psychologically.
- Extrapersonal interactions. T e reaction of the pediatric patient to the treating clinician and the conditions under which the pediatric patient is observed.
- Age-related changes in muscle and muscle performance.
- T e developing skeletal system. Examination of the pediatric patient requires an understanding of, and an awareness of, the timing of growth center appearance and epiphyseal closure. For example, the sequence and average timing of growth center appearance at the elbow are as follows[5]:
  - Capitellum. Female, 4 months; male, 5 months.
  - Medial epicondyle. Female, 5 years; male, 7 years.
  - Trochlea. Female, 8 years; male, 9 years.
  - Lateral epicondyle. Female, 11 years; male, 12 years.

TABLE 30-2 Differences in Adolescent Females Compared to Males

Anatomic	Physiologic
Reduced muscle fiber size	Increased percentage of body fat (10–15 lb more)
Wide hips with narrower shoulders	Women have 40–45 less pounds of fat-free weight (bone, muscle, organs)
Shorter height (3–4 in on average)	Basal metabolic rate is relatively lower
Relatively smaller total articular surface area	Reduced testosterone levels
Relatively more fat around the thighs and hips	Skeletal maturation occurs earlier
Heart size and volume are smaller	Aerobic capacity is lower
Lung volume is smaller	Vital capacity is less

Epiphyseal closure at the elbow occurs sequentially, first in the distal humerus, with the capitellum, lateral epicondyle, and trochlea fusing together at puberty (female, 14 years and male, 17 years), then fusing with the shaft.[5] T e medial epicondyle fuses later (female, 15 years and male, 18 years). T e radial head and olecranon close at 14 years in females and 15 years in males.[5]

Growing musculoskeletal tissue is innately predisposed to specific injuries that vary greatly from injuries sustained by their skeletally mature counterparts. Most of this growth occurs in two phases from birth to adulthood. T ere is a rapid gain in growth in infancy and early childhood that slows down during middle childhood. T e second rapid increase in growth occurs during adolescence. An injury that occurs during one of these phases, which is significant enough to interrupt the growth process, can present serious challenges.

CLINICAL PEARL

The main goals of physical therapy intervention in pediatric rehabilitation are to reduce barriers limiting the performance of daily routines and to facilitate the successful integration of children into the home, play, and school environments. Therapeutic exercise that is prescribed for the pediatric patient must be creative, and attempts must be made to try to make exercise fun in order to increase compliance. In addition, special consideration must be given when prescribing exercise due to the number of growth changes that are occurring[6]:

- ≤ 7 years: an introduction to basic exercises, teaching correct technique using low-volume and little or no weight. For example, 1–3 sets of 6–15 repetitions.[7]
- 8–10 years: gradual increase of the number of exercises and progressive loading using simple exercises. Loads should be increased in 1–3 -lb increments after

the child can perform 15 repetitions with proper form.[7] Resistance equipment that can be adapted to the size of the child should only be used.

- 11–13 years: teach all basic exercise techniques and continue progressive loading. More advanced techniques/exercises can be introduced with little or no resistance.
- 14–15 years: more advanced youth programs and resistance exercise with sport-specific components.
- ≥ 16 years: entry-level adult programs

ACQUIRED ORTHOPAEDIC CONDITIONS

Musculoskeletal injuries in individuals with an immature musculoskeletal system require a different set of considerations than injuries in adult individuals—children are not small adults.[8] There is currently a concern that the increase in sports participation exposes children to a higher risk of musculoskeletal injuries that may negatively influence long-term health.[8,9] In the developing skeleton, the epiphyseal growth plates are especially vulnerable, and injuries to these may result in significant limb-length discrepancies and angular deformities.[8,10]

Skeletal Fracture

The mechanical properties and healing qualities of skeletal bone are described in Chapters 1 and 2, respectively. In the pediatric population, the metaphysic–physis junction is an anatomic point of weakness. Fractures of bone in pediatric patients may be due to direct trauma, such as a blow, or indirect trauma, such as a fall on the outstretched hand (FOOSH injury), or a twisting injury. Three types of fractures occur more commonly in the pediatric population:

- Greenstick. A type of simple fracture in which only one side of the bone is fractured while the opposite side is bent. Because the bones in a pediatric patient have not fully developed, they are less rigid and brittle. This type of fracture tends to heal faster than other types.
- Avulsion. Avulsion occurs when a piece of bone attached to a tendon or ligament is torn away. In the younger population, ligaments and tendons are stronger than bone. When changes in muscle length do not match the changes in long-bone growth, tensile loads placed within the muscle predispose the pediatric patient to injury. Lower extremity avulsion fractures outnumber avulsion fractures of the upper extremity (UE). Common sites of avulsion fracture in the lower extremity include the anterior superior iliac spine (ASIS), anterior inferior iliac spine (AIIS), ischial tuberosity, and the base of the fifth metatarsal. Common sites of avulsion fracture in the UE include the medial humeral epicondyle and the proximal humerus. If a medial epicondyle avulsion fracture is suspected, it is important to assess the ulnar nerve, and for the presence of point tenderness over the medial epicondyle, swelling, ecchymosis, and valgus instability.
- Growth plate (physeal). This type of fracture involves an interference in the cartilaginous physis of long bones that may well or may not involve the metaphyseal or epiphyseal bone. The physis is the weakest link in the immature skeleton, and the open growth plates in long bones and at the apophysis make physeal injuries more likely to occur in the pediatric population, also in part due to the greater structural strength and integrity of the ligaments and joint capsules than of the growth plates and the fact that the physes of an adult have ossified. The morbidity and sequelae of a missed physeal injury are not easily remedied. Growth plate fractures can have severe consequences because of the potential for growth plate closure, which inhibits future longitudinal or angular growth resulting in limb-length discrepancies. Conversely, an injury near, but not at, the physis can stimulate increased bone growth.

With the increasing involvement of youth in organized sports, overuse injuries are becoming a frequent reality among children. The peak incidence of traumatic physeal injury is 11–12 years in girls, and 13–14 years in boys.[11]

The Salter and Harris classification is the preferred and accepted standard in North America for classifying physeal fracture patterns[3]:

- *Type I.* This type, which involves only the physis, occurs due to shearing forces in which there is complete separation of the epiphysis without fracture of the bone. These fractures are most commonly seen in the very young patient when the epiphyseal plate is relatively thick.
- *Type II.* This is the most common type of growth plate fracture resulting from shearing and bending forces. The line of separation traverses a variable distance along the epiphyseal plate and then makes its way through a segment of the bony metaphysis that results in a triangular-shaped metaphyseal fragment (also known as a Thurston Holland fragment).
- *Type III.* This is typically results from shearing forces and results in intraarticular fractures from the joint surface to the deep zone of the growth plate and then along the growth plate to its periphery. These fractures are typically limited to the proximal tibial/distal femoral epiphysis and can result from valgus loading of the knee, which is frequently encountered in contact and collision sports.
- *Type IV.* These are intraarticular fractures that result from shearing forces. These fractures extend from the joint surface to the epiphysis across the entire thickness of the growth plate and then through a segment of the bony metaphysis. Management of these fractures is complex.
- *Type V.* These types of fractures, which are due to a crushing mechanism, are relatively uncommon.

The risk of growth disturbance is highest with types III, IV, and V fractures.

CLINICAL PEARL

The most common of the Salter–Harris fractures is II, followed by I, III, IV, and V.

Clinical Findings

T e most common clinical presentation with a pediatric fracture is pain, weakness, and functional loss of the involved area. T e most common areas for epiphyseal fracture include the distal radius and the medial epicondyle, the proximal humerus, and the proximal tibia/distal femoral.

Intervention

In most cases, the medical management of a fracture involves immobilization through casting, splints, or surgical fixation to allow full healing to occur. Pediatric fractures tend to heal faster than an equivalent one in an adult. T is can be advantageous: Children typically require shorter immobilization times. A disadvantage, however, is that any malpositioned fragments become immovable or fixed much earlier than in adults (3–5 days in a young child, 5–7 days in an older child, as opposed to 8–10 days in an adult). However, the normal process of bone remodeling in a child may correct malalignment, making near-anatomic reductions less important in children than in adults. Remodeling can be expected if the patient has two or more years of bone growth remaining. Rotational deformity remodels poorly, if at all, and is therefore corrected by surgical reduction. A further complication is that pediatric fractures may stimulate a longitudinal growth of the bone, making the bone longer than it would have been had it not been injured. T is is particularly true for fractures of the femoral or tibial shaft.

Children tolerate prolonged immobilization much better than adults and disabling stiffness or loss of range of motion (ROM) is distinctly unusual after pediatric fractures. Physical therapy, if needed, typically begins after the immobilization period, and depending on the type and location of the fracture, it can involve any or all of the following:

- Pain management techniques including the use of noncontraindicated electrotherapeutic modalities (see Chapter 8) and manual techniques, including joint mobilizations.
- ROM exercises, following the hierarchy of progression outlined in Chapter 13.
- Strengthening exercises, beginning with isometrics and progressing using the hierarchy of progression outlined in Chapter 12.
- Gait and/or crutch training with an appropriate assistive device and following the prescribed prescription for weight bearing (see Chapter 6).
- Proprioception exercises for balance and coordination (see Chapter 14).
- Functional training including adaptive, supportive, or protective devices and activities of daily living (ADLs) and self-care.
- Patient and family education to decrease the risk of re-injury and to promote healing.

ACL Injury

ACL injuries are among the most severe and most frequent activity-related injuries sustained by active children.[12] Life-long knee function and quality of life (QoL) may also be affected due to a probable increase in the risk of developing early knee OA.[8,13,14] T ere are two major challenges in the management of ACL injuries in the skeletally immature population[8,15]:

- to safely implement treatment interventions that provide the best possible long-term functional outcomes and,
- to reduce the risk of secondary meniscus injury or harm to the epiphyseal growth plates.

CLINICAL PEARL

The catch 22 of ACL surgery is that the procedure involves the risk of the iatrogenic growth disturbances while nonoperative treatment may involve an increased risk of secondary meniscus and cartilage injuries.[8]

T e distal femoral physis is the most active growth plate in the human body, contributed approximately 1 cm of growth per year, which in turn is responsible for 70% of the longitudinal growth of the femur and 37% of the growth of the lower limb.[16] T e proximal tibial physis contributes approximately 0.7 cm of growth per year, which equals 55% of tibial growth and 25% of lower limb growth.[16]

T e mechanism of ACL injury is similar to that as in adults (see Chapter 20), with the most common being Alpine skiing and playing soccer. However, unlike with adults, the diagnostic accuracy of acute knee injuries in children is less certain, which may be explained by the fact that the knees of children have greater ligamentous laxity than those of adults.[17,18] T us, the combination of injury history, clinical examination (including the Lachman test and pivot shift test—see Chapter 20), and MRI is recommended to optimize the diagnostic accuracy of ACL injuries in the skeletally immature.[8,19]

T e traditional approach to ACL injuries in the skeletally immature consisted of nonoperative management of active rehabilitation, activity limitations, and bracing until the child's skeleton had neared the end of its growth.[20,21] However, newer surgical techniques have allowed for early ACL reconstruction. T e two most common surgical approaches for this population include[8]

- transphyseal ACL (adult) reconstruction, which requires the surgeon to drill a hole through both the proximal tibial physis and distal femoral physis to enable an anatomical reconstruction of the native ACL.
- physeal sparing ACL reconstruction, which occurs when the surgical procedure does not involve drilling graft holes through the epiphyseal growth plates.[8]

T e postsurgical management program consists of exercises targeted toward regaining ROM, neuromuscular control, and muscle strength.

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA) is a group of diseases that are manifested by chronic joint inflammation [22,23] JRA is defined as persistent arthritis, lasting at least 6 weeks, in one or more joints in a child younger than 16 years of age, when all other causes of arthritis have been excluded.

T e descriptive term juvenile idiopathic arthritis was adopted as an umbrella term to indicate a disease of childhood onset, characterized primarily by arthritis of no known etiology persisting for at least 6 weeks. JRA is the most prevalent pediatric rheumatic diagnosis among children in the United States. T e exact etiology of JRA remains unclear, but the prevailing theory is that it is an inflammatory autoimmune disorder, activated by an external trigger, in a genetically predisposed host. JRA is classified as a systemic, pauciarticular, or polyarticular disease, according to onset within the first 6 months. T e general history of JRA includes the following:

- Disease onset is either insidious or abrupt, with morning stiffness and arthralgia during the day.
- Individuals with JRA may have a school history of absences, and their abilities to participate in physical education classes may reflect the severity of the disease. Typically, patients with JRA and their parents and/or caregivers are concerned about missing school; in contrast, when psychogenic factors predominate (e.g., pain syndromes), patients and their parents and/or caregivers are more worried about returning to school than about missing school.
- Limping may be observed in individuals with more severe JRA; however, the presence of limping also raises the possibility of trauma or another orthopaedic problem.
- Injury suggests the possibility of trauma to a joint (e.g., meniscal tear).
- A preceding illness raises the possibility of the infectious trigger of JRA or postinfectious arthritis.
- Illness onsets with a history of enteritis raise the possibility of reactive arthritis.
- History of travel with exposure to ticks raises the possibility of arthritis caused by Lyme disease.
- Gastrointestinal symptoms raise the possibility of inflammatory bowel disease.
- Very severe joint pain raises the possibility of acute rheumatic fever (also suggested by migratory but not additive arthritis, with fevers), acute lymphocytic leukemia (with metaphyseal pain on examination and a decrease in two or more cell lines), septic arthritis, or osteomyelitis.
- Weight loss without diarrhea may be observed in individuals with active JRA and is sometimes associated with anorexia. T is symptom is also observed in individuals with acute lymphocytic leukemia with other obvious findings (e.g., severe bone pain).
- Weight loss with diarrhea may be observed in persons with inflammatory bowel disease.
- Photophobia may be observed in persons with usually asymptomatic uveitis.
- Orthopnea suggests pericarditis in children with systemic JRA; the differential diagnosis includes systemic lupus erythematosus (SLE) and viral pericarditis.
- Systemic-onset JRA is characterized by spiking fevers, typically occurring several times each day, with temperature returning to the reference range or below the reference range.
- Systemic-onset JRA may be accompanied by an evanescent rash, which is typically linear, affecting the trunk and extremities.
- Arthralgia is often present. Frank joint swelling is atypical; arthritis may not occur for months following onset, making diagnosis difficult.
- T e pauciarticular disease is characterized by arthritis affecting four or fewer joints.
- Typically, larger joints (e.g., knees, ankles, and wrists) are affected.
- Monoarticular arthritis in a hip is highly unusual.
- When the knee is affected, limping may be noted, particularly in the mornings.
- T e polyarticular disease affects at least five joints.
- Both large and small joints can be involved, often in symmetric bilateral distribution.
- Severe limitations in motion are usually accompanied by weakness and decreased physical function.
- Some children may have a generalized myalgia.
- Localization to the proximal muscles raises the possibility of a myositis.
- Consider slipped capital femoral epiphysis (SCFE) or chondrolysis of the hip in an older child, or osteomyelitis, Legg–Calvé–Perthes disease, toxic synovitis of the hip, or septic arthritis in the younger child.

Chronic involvement can result in atrophy of extensor muscles in the thigh, tight hamstring muscles, and knee flexion contractures.

A detailed physical examination by a physician is a critical tool for diagnosing JRA to help rule out other causes.

Intervention

Physical therapists are essential members of the rheumatology team that includes the rheumatologist, nurse, occupational therapist, ophthalmologist, orthopaedist, and pediatrician.[24] Other specialists, including cardiologists, dermatologists, orthotists, psychologists, and social workers, provide occasional consultation as needed. T e physical therapy examination is performed to determine the relationship between the impairments and observed or reported activity restrictions. T e plan of care (POC) is designed to reduce current impairments, maintain or improve function, prevent or minimize secondary problems, and provide education and support to the child and family. Specific interventions can include any or all of the following:

- ROM and stretching exercises.
  - Acute stage: passive and active assisted exercises to avoid joint compression.
  - Subacute/chronic stages: active exercises.
- Strengthening: avoid substitutions, minimize instability, atrophy, deformity, pain, and injury.
  - Acute and subacute stages: isometric exercises are progressed cautiously to resistive.
  - Chronic stage: concentric exercises.
- Endurance exercises: encouraging exercise by using fun and recreational activities, swimming.

- Joint protection strategies and body mechanics education.
  - Mobility assistive devices.
  - Rest, as needed—balance rest with activity by using splinting (articular resting).
  - Posture and positioning to maintain joint ROM.
  - Patients should spend 20 minutes/day in the prone position to stretch the hip and knee flexors
  - Avoidance of high-impact activities.
  - Assess leg-length discrepancy in standing and avoid scoliosis.
- Therapeutic modalities for pain control.
- Instructions on the wearing of warm pajamas, sleeping bag, electric blanket.

Idiopathic Scoliosis

The overall contour of the normal vertebral column in the coronal plane is straight. In contrast, the contour of the sagittal plane changes with development (see Chapter 22).[25–30] Scoliosis represents a progressive disturbance of the intercalated series of spinal segments that produces a three-dimensional deformity (lateral curvature and vertebral rotation) of the spine. Despite an extensive amount of research devoted to discovering the cause of idiopathic scoliosis, the mechanics and specific etiology are not clearly understood, hence the name. It is known, however, that there is a familial prevalence of idiopathic scoliosis.

Clinical Findings

Using the James classification system, scoliosis has three age distinctions. These distinctions, though seemingly arbitrary, have prognostic significance.

- Infantile idiopathic. Children diagnosed when they were younger than 3 years, usually manifesting shortly after birth. Although 80–90% of these curves spontaneously resolve, many of the remainders of cases will progress throughout childhood, resulting in severe deformity. In the most common curve pattern (right thoracic), the right shoulder is rotated anteriorly, and the medial border of the right scapula protrudes posteriorly.
- Juvenile idiopathic. Children diagnosed when they are 3–9 years. This type is found more frequently in girls than boys, and individuals that develop this condition are generally at a high risk for progression to more severe curves.
- Adolescent idiopathic. Manifesting at or around the onset of puberty and accounting for approximately 80% of all cases of idiopathic scoliosis.

The following are the main factors that influence the probability of progression in the skeleton of the immature patient:

- The younger the patient at diagnosis, the greater the risk of progression.
- Double-curve patterns have a greater risk for progression than single-curve patterns.
- Curves with greater magnitude are at a greater risk to progress.
- The risk of progression in females is approximately 10 times than that of males with curves of comparable magnitude.
- Greater risk of progression is present when curves develop before menarche.

Scoliosis is generally described by the location of the curve or curves. One should also describe whether the convexity of the curve points to the right or left. If there is a double curve, each curve must be described and measured. As the disease progresses, the spinous processes of the vertebrae in the area of the major curve rotate toward the concavity of the curve. On the concave side of the curve, the ribs are close together. On the convex side, they are widely separated. As the vertebral bodies rotate, the spinous processes deviate more and more to the concave side, and the ribs follow the rotation of the vertebrae. The ribs on the convex side are rotated more posteriorly, causing the characteristic rib hump seen in thoracic scoliosis. The ribs on the concave side are rotated more anteriorly. Because the onset and progression of scoliosis (until skeletal maturity) are generally asymptomatic, it can develop undetected without close examination.

The significant incidence of scoliosis in the adolescent population has prompted the creation of school screening programs in all 50 states. Visual observation is used during the Adam's forward bending test, which involves asking the patient to bend forward at the waist as though touching his or her toes while the clinician, who is standing behind the patient, looks along the line at the back and determines whether one side is higher than the other. If scoliosis is suspected, the magnitude of a rib hump is quantified by placing a scoliometer (an inclinometer) over the spinous process at the apex of the curve during the Adam's forward bending test to measure the angle of trunk rotation as the patient bends forward. During the physical examination by the patient's physician, a determination is made as to whether the deformity is structural (cannot be corrected with active or passive movement and there is rotation toward the convexity of the curve) or nonstructural (fully corrects clinically and radiographically with trunk side bending toward the apex of the curve and lacks vertebral rotation). Nonstructural scoliotic curves can result from length–length discrepancies, muscle disuse/overuse, habitual postures, and muscle guarding.

Height measurements are taken in sitting and in standing. Changes in sitting height can be less than changes in standing height and give a better estimate of truncal growth rate. Trunk compensation is typically assessed using a plumb-line, and a radiographic leg-length measurement is also obtained.

CLINICAL PEARL

Radiographs, which are usually only considered when a patient has a curve that might require treatment or could progress to a stage requiring treatment, can be used to determine location, type, and magnitude of the curve (using the Cobb method), as well as skeletal age. Alternatively, a noninvasive (reduces radiation exposure) technique called Moiré topography can be used, in which light is projected through grids onto the back of the patient to assess topographical asymmetry.

Skeletal maturity is determined using the Risser sign, which is a measurement of the progressive ossification from anterolaterally to posteromedially in the iliac apophysis. Once a child reaches a grade 5 on the Risser scale, his or her scoliotic curve will stabilize. A child with idiopathic scoliosis usually progresses from a Risser grade 1 to a grade 5 over a 2-year period.

CLINICAL PEARL

If scoliosis is neglected, the curves may progress dramatically, creating significant physical deformity and even cardiopulmonary problems with especially severe curves. Pulmonary function tests are warranted in the presence of severe curves due to the resultant rib cage restrictions and decreased chest wall expansion.

Most curves can be treated nonoperatively with observation and periodic radiographs to check for the presence of curve progression. However, approximately 60% of curvatures in rapidly growing prepubertal children typically progress, and may require bracing (Boston or custom thoracolumbosacral orthosis) or surgery.

CLINICAL PEARL

Orthoses are typically prescribed for children with idiopathic scoliosis who are skeletally immature (with a Risser sign of 0, 1, or 2) and have a curve from 25 to 45 degrees. The active theory of orthotics is that curve progression is prevented by muscle contractions responding to the brace wear. Exercises to be performed while wearing a brace, such as pelvic tilts, thoracic flexion, and lateral shifts, are often taught to patients to improve the active forces, although there is little evidence to support this.

Intervention

Physical therapy intervention for scoliosis is based on the skeletal maturity of the child, the growth potential of the child, and the magnitude of the curve. The primary benefits of exercise in a nonsurgical patient with scoliosis are as follows[31]:

- Help with correct postural alignment and any asymmetrical postural habits to prevent further development following the bracing program.
- Maintain proper respiration and chest mobility.
- Improve overall spinal mobility and to help reduce back pain.
- Help the patient resume prebracing functional skills.
- Maintain muscle strength, particularly in the abdominals.
- Maintain or improve correct length and strength relationships of the spinal and extremity musculature. The general rule is to strengthen the muscles on the convex side and to stretch the muscles on the concave side. Asymmetric exercise is used to promote symmetry. For example, in a patient with a right thoracic, left lumbar curve, typical findings may include weakness of the right iliopsoas and right external oblique. Exercises that could be prescribed for this patient would include resisted right hip flexion at the end range with the patient sitting to address the weakness of the right iliopsoas. A weakness of the right external oblique can be addressed using a left UE diagonal reaching movement pattern emphasizing right thoracic side bending (Fig. 30-1). Other functional exercises for scoliosis include the following:
  - The patient is positioned in prone and is asked to place both hands above his or her head while deviating the thorax away from the concave side of the curve (Fig. 30-2).
  - The patient is positioned in supine and is asked to reach overhead and extend the arm on the concave side (Fig. 30-3).
  - The patient is positioned in heel-sitting and is asked to place both hands forward and flat while emphasizing

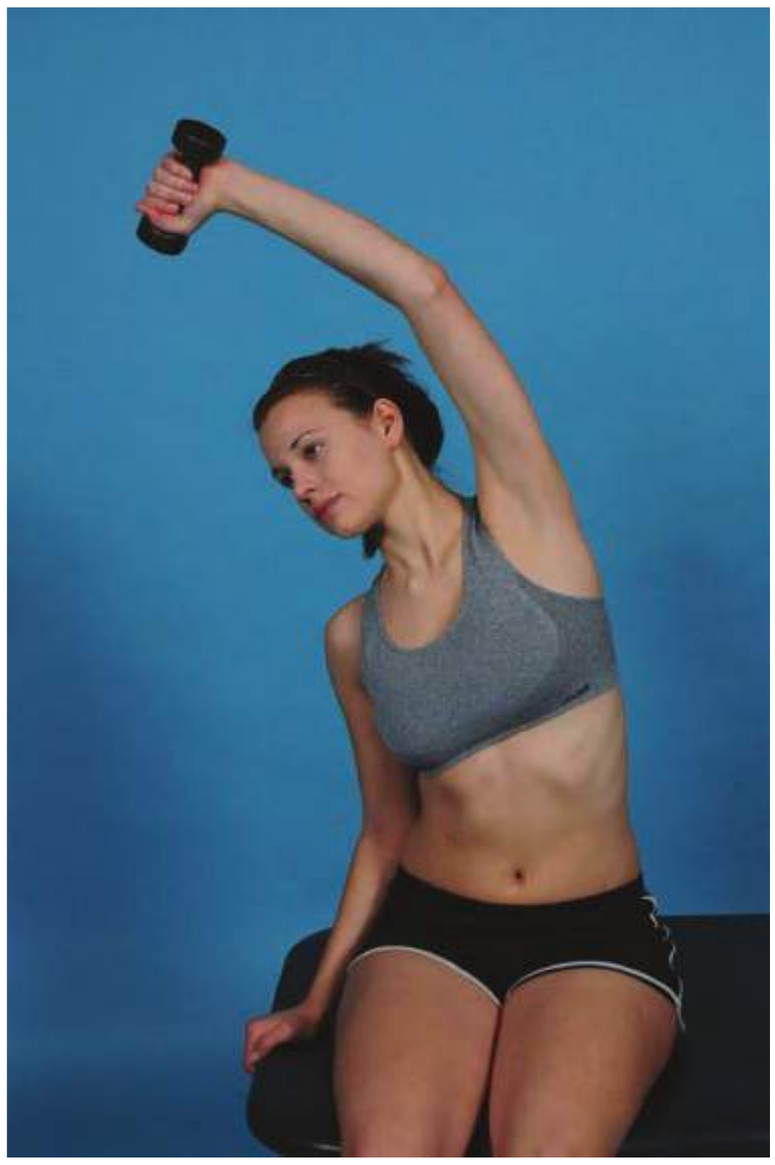

FIGURE 30-1 Left upper extremity diagonal reaching movement pattern emphasizing right thoracic sidebending.

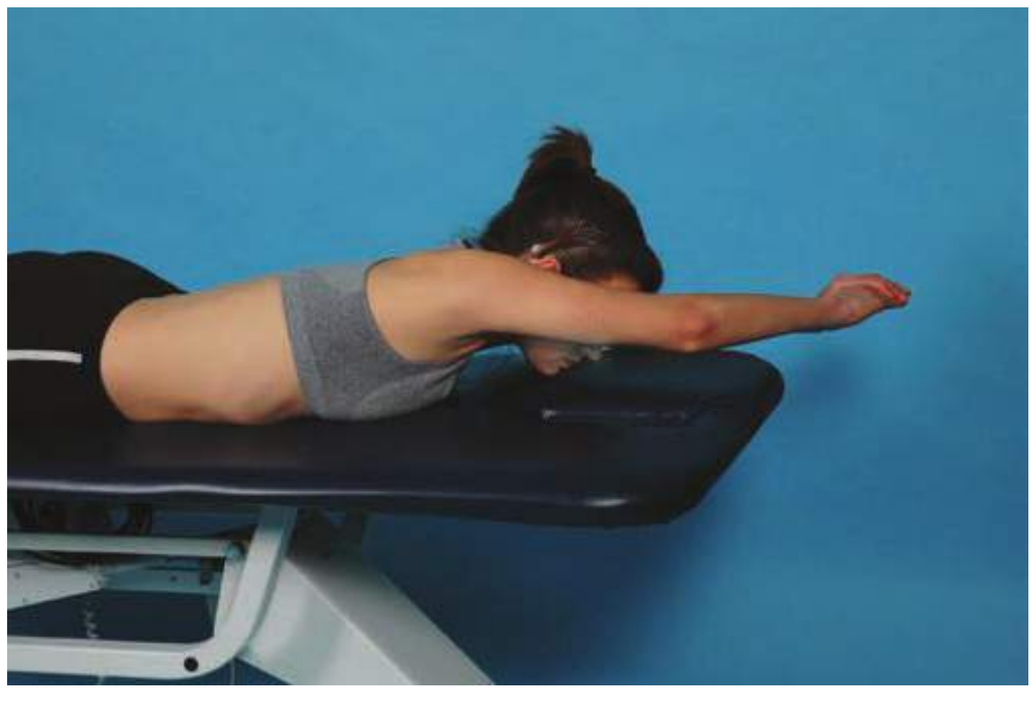

FIGURE 30-2 Prone sidebending with arms overhead.

FIGURE 30-3 Prone sidebending by reaching overhead with one hand.

trunk axial elongation (Fig. 30-4). T e patient is then asked to stretch both arms laterally away from the concave side of the curve.

- T e patient is positioned in side lying (convex side down) over the end of the table with a hand to provide balance (Fig. 30-5). A pillow can be placed directly under the apex of the convex thoracic curve. Once in this position, the patient is asked to reach overhead and then down toward the floor using the arm that is closest to the ceiling to enhance the stretch.
- Swiss ball exercises can also be used, focusing on gaining increased thoracic side bending, while stretching the concave side (Fig. 30-6).
- Any of the strengthening exercises described in the intervention strategy section of Chapter 27 can be used to

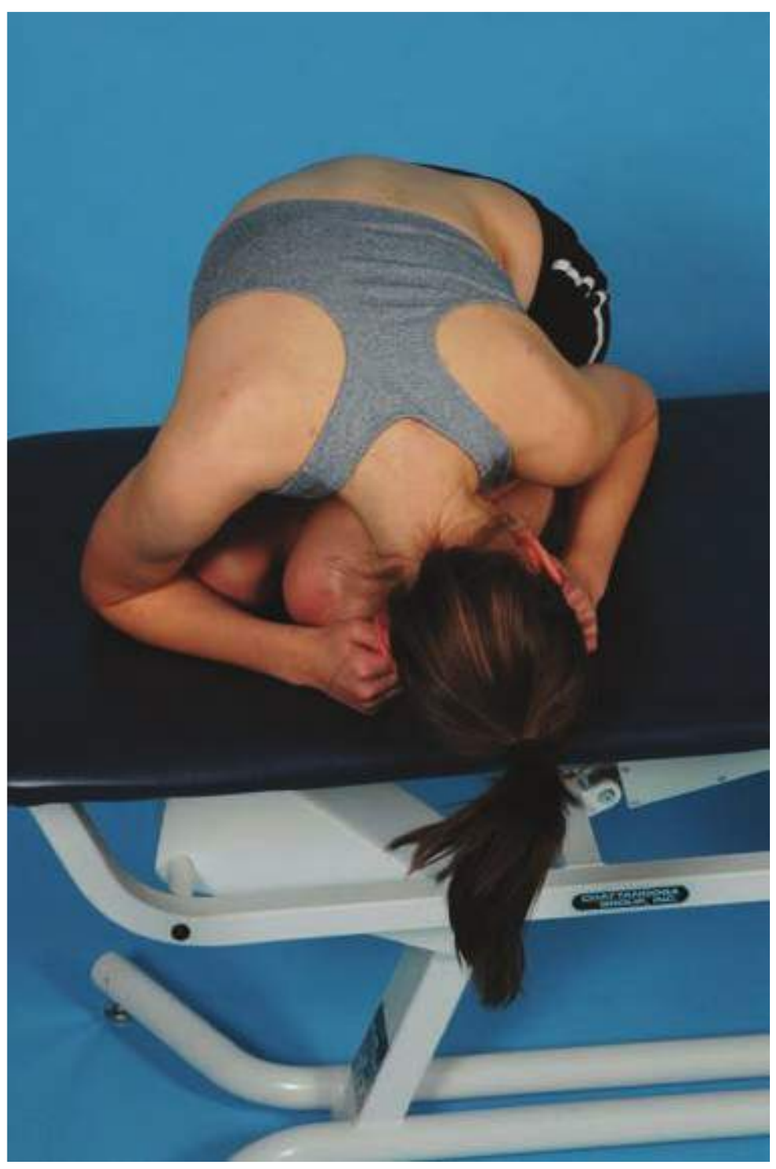

FIGURE 30-4 Prone heel sitting with forward flexion and sidebending.

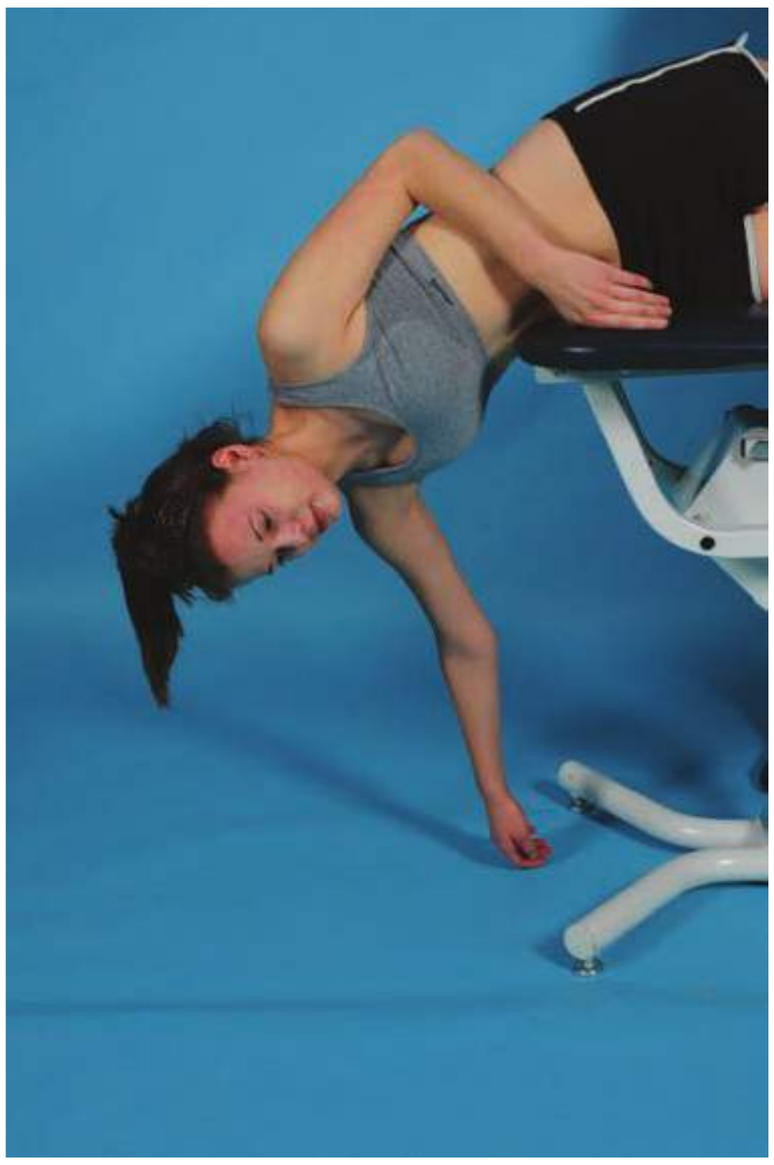

FIGURE 30-5 Side lying over the edge of a table to accentuate thoracic curve.

increase strength in the extensor muscle groups. Side-lying techniques (lying on the concave side) can be incorporated to strengthen the lateral muscle groups. T e side-lying sit-up exercise is particularly effective (Fig. 30-7).

If surgery is considered, the primary goal of scoliosis surgery is to achieve a solid bony fusion. T e postsurgical management includes the previously mentioned strategies and the following[32]:

- Breathing exercises to promote rib cage expansion, pulmonary hygiene, and effective coughing.
- Patient and family education.

Developmental Dysplasia of the Hip

Up to 10% of infants in the United States are born with a congenital dislocation of the hip.[33] T e acronym CDH is

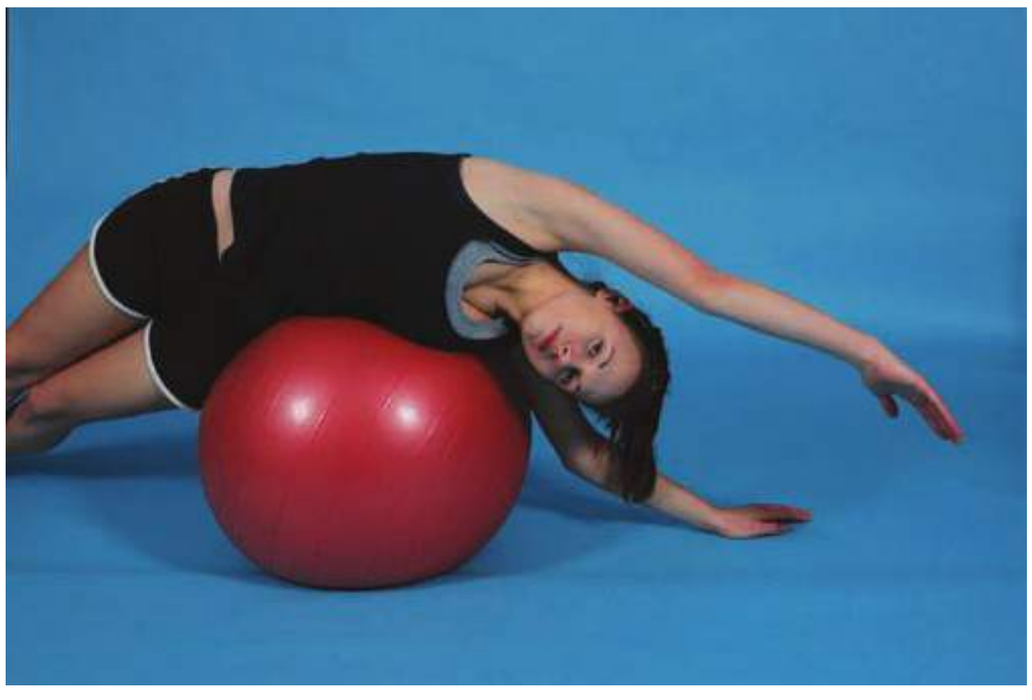

FIGURE 30-6 Swiss ball sidebending to accentuate thoracic curve.

FIGURE 30-7 Side lying sit-up exercise.

confusing and has been used synonymously with congenital dislocation or congenital disease of the hip. A dislocated hip is a physical sign, not a diagnosis, and the term congenital means present at birth.[34]

Thus, the acronym DDH is replacing CDH. The word developmental invokes the dimension of time, acknowledging that the dysplasia or dislocation may occur before or after birth while dysplasia means an abnormality of development and encompasses a wide spectrum of hip problems.[34]

DDH includes hips that are unstable, malformed, subluxated, or dislocated. Instability is the inability of the hip to resist an externally applied force without developing a subluxation or dislocation.[34] A subluxation is an incomplete dislocation with some residual contact between the femoral head and acetabulum, whereas a dislocation indicates complete displacement of the femoral head from the acetabulum.[34]

The etiology of DDH is felt to be multifactorial, including both mechanical and physiological factors. In utero, the hip is in a position of flexion and abduction that results in a tightened iliopsoas tendon and anterior–lateral orientation of the acetabulum.[35] The tight iliopsoas may push the femoral head out posteriorly with hip extension during kicking. The labrum (cartilaginous rim of the acetabulum) becomes everted and flattened.

The acetabulum and femoral head develop rapidly in the neonatal period. When the acetabulum and femoral head are in the correct position, each reinforces the development of the other by this physical contact; however, if the hip is not concentrically reduced, it will develop in a dysplastic manner.[36–38] If the hip reduces spontaneously within a few days, hip development usually proceeds normally. In contrast, if a subluxation or dislocation persists, the femoral head becomes flattened on the posteromedial surface, the acetabulum becomes shallow and dysplastic, and femoral anteversion gradually increases.[36–38] In addition, the muscles surrounding the hip may shorten and contract.

Prolonged dislocation makes it difficult to return the femoral head to the acetabulum and is associated with a higher incidence of OA and impaired hip function in adulthood.[33]

Clinical Findings

The value of the neonatal hip screening examination remains controversial.[34] At present, tests including the ones outlined below are currently used to examine the infant. The examination requires patience and skill, and the newborn must be relaxed on a firm surface.

The examiner attempts to reduce the dislocation or subluxation using the Ortolani and Barlow maneuvers.[34]

With the newborn supine, the clinician places the tips of the long and index fingers over the greater trochanter, with the thumb along the medial thigh. The infant's leg is positioned in neutral rotation with 90 degrees of hip flexion and is gently abducted while lifting the leg anteriorly.[34] With abduction one can feel a clunk, as the femoral head slides over the posterior rim of the acetabulum and into the socket. This is the clunk originally described by Ortolani,[39] and is called the sign of entry, as the hip relocates with this maneuver. Maintaining the same position, the leg is then gently adducted, while gentle pressure is directed posteriorly on the knee, and a palpable clunk is noted as the femoral head slides over the posterior rim of the acetabulum and out of the socket.[34] This clunk was originally described by Barlow,[40] and is called the sign of exit, as the hip dislocates with this maneuver. Both tests are designed to detect motion between the femoral head and the acetabulum.[34] The reproducibility of these tests is dependent on ligamentous or capsular laxity, which usually disappears by the age of 10–12 weeks.[34]

Clinical screening programs are important in reducing the incidence of surgery. Ultrasound is the diagnostic modality of choice.[41] Early intervention has been reported to lead to a successful outcome in 90% and 96% of children radiographically and functionally, respectively.[36–38] Later examinations include assessment of gluteal folds, knee height, and the degree of hip abduction.[42] In the 3- to the 12-month-old infant, the best physical finding is a limitation of hip abduction. In the supine position, with the hip in 90 degrees of flexion and one hand stabilizing the pelvis, each hip should easily abduct to 75 degrees and adduct to 30 degrees past the midline.[34] In the older child, a limp, positive Trendelenburg, toe-walking, in-toeing, or out-toeing may be secondary to DDH.[34]

Intervention

The treatment of this condition depends on the age of the patient and the severity of the condition. The goal of the intervention is to obtain and maintain a concentric reduction of the hip to provide an environment for normal bony development. The conservative approach is most effective for infants whose subluxation or dislocation have been discovered and treated early, within the first 6 months of life. The conservative approach involves maintaining the hip in flexion and abduction through diapering, and bracing/splinting until it is adequately remodeled.

- Diapering. The child is placed in two to three diapers, which is designed to hold the legs in abduction, and parents are instructed to position the infant in hip flexion as well.
- Pavlik harness. The preferred conservative intervention is an outpatient intervention regimen using the Pavlik harness that provides an effective reduction in 90% of the cases.[42] However, the harness is ineffective after 3 weeks making early detection critical. In infants older than 9 months who are beginning to walk independently, an

abduction orthosis can be used as an alternative to the Pavlik harness.[43] T e harness, which is initially worn 24 hours a day for 6–12 weeks, is used if symptoms persist after several weeks and is designed to restrict hip extension and adduction while allowing the hip to be maintained in flexion and abduction.[43] T is "protective position" of flexion and abduction enhances normal acetabular development, and the kicking motion allowed in this position stretches the contracted hip adductors while promoting spontaneous reduction of the dislocated hip.[43] After the initial period, the harness is worn 12 hours per day for 3–6 additional months or until both clinical and radiographic signs are normal. If the Pavlik harness is used, it is important to teach the parents that the hips are placed in the correct position—too much flexion or abduction can cause excessive pressure through the femoral heads, resulting in possible avascular necrosis.

In more severe cases, skin traction and spica-cast application may be needed. Open and closed reduction and recasting are also options.

Legg–Calvé–Perthes Disease

T e development of the hip is influenced by both genetic and mechanical factors. Since the embryonic period is a time of determination of anatomical configuration, congenital abnormalities may occur during this period. By the 11th week, the hip is held in the fetal position of flexion, abduction, and external rotation. Although the basic shape of the skeletal system is well established by the fetal period, bones continue to increase in size until skeletal maturity. At the hip, the proximal femur grows in three areas which include the apophyseal growth of the greater trochanter, the femoral neck isthmus, and the physial plate. While the hip joint is fully formed by the 11th week of gestation, the acetabulum continues to evolve throughout gestation and into childhood. T us, the watershed age for prognosis of pediatric hip conditions is 8 years old, as this is the age when most acetabular development is complete.[44] After 8 years of age, accommodation of acetabular shape to a deformed femoral head may not be possible.

Legg–Calvé–Perthes disease, a disorder of the hip in young children, was described around the turn of the century, independently by Legg, Calvé, Perthes, and Waldenström.[44] T e incidence of Perthes disease varies considerably from place to place. Low rates of around 5 or 6 per 100,000 have been reported from British Columbia, Massachusetts, and rural Wessex, England, whereas rates of between 11 and 15.6 per 100,000 have been found in Liverpool, England.

T ere is considerable epidemiologic, histologic, and radiographic evidence to support the theory that Legg–Calvé–Perthes disease is probably a localized manifestation of a generalized disorder of epiphyseal cartilage manifested in the proximal femur because of its unusual and precarious blood supply.[45,46]

T e definitive cause of Legg–Calvé–Perthes disease remains unknown. Many etiologic theories have been proposed. Most current etiologic theories involve vascular embarrassment, with repeated episodes of infarction and ensuing abnormalities.[47]

Clinical Findings

T e onset is usually insidious, and the course is prolonged over a period of several years. T e initial sign is a limp. T e child may be small for his/her age. T ere may also be a slight dragging of the leg and slight atrophy of the thigh muscles. A positive Trendelenburg sign is often seen. T ere may be some out-toeing of the involved extremity. T e patient complains of a vague ache in the groin that radiates to the medial thigh and inner aspect of the knee. Muscle spasm is another common complaint in the early stages of the disease. On examination, there is usually decreased abduction and internal rotation. T e ROM examination may show contracture in hip flexion and adduction.

Intervention

T e intervention for Legg–Calvé–Perthes disease remains controversial.[43] T e goal of treatment is to relieve pain and to maintain the spherical shape of the femoral head and to prevent extrusion of the enlarged femoral head from the joint. Children who are less than 6 years of age (possibly 5 years in girls) and those with minimal capital femoral epiphysis involvement and normal ROM are often followed with intermittent physical examinations and radiographs approximately every 2 months. In the more severe cases, there is a lack of agreement regarding whether operative or nonoperative intervention is beneficial.[44] In reviewing long-term studies, it is apparent that the results improve with time.[48,49] Most patients (70–90%) are active and pain-free regardless of intervention. T e prognosis is much improved if there is no collapse of the femoral head. An important aspect in the intervention is the containment of the femoral head in the acetabulum. T is is ensured by maintaining the hip in abduction and mild internal rotation for an extended period, using the Atlanta Scottish-Rite Hospital Orthosis. Although this brace does not use internal rotation-like casts as some other orthosis do, it does maintain the hip in abduction and permits approximately 90 degrees of hip flexion. T is allows the patient to run and ride a bicycle while wearing the brace.[50] It is worth noting that forced abduction treatment can lead to damage to the lateral physis.[51,52] T e advantages of operative intervention for containment of the femoral head are a short time of restriction of movement, a more permanent containment, and perhaps enhanced remodeling of the femoral head.

Physical therapy may be provided at home, school, or in the clinic. Treatment methods include

- observation only;
- ROM exercises in all planes of hip motion (especially internal rotation and abduction);
- bracing; and
- casting.

Specific procedural interventions can be used to relieve the forces incurred during weight bearing (crutch training, aquatic therapy). Gait training may be initiated with an orthosis or with bracing. T e specific gait pattern and assistive devices depend on the type of orthosis. Patient and family education is necessary to teach hip protection strategies, thereby minimizing degenerative changes as the child ages.

Transient Synovitis

T is is the most common cause of hip pain and of limp in preschool and early grade school-age children. Transient synovitis is also known as toxic synovitis, irritable hip, and observation hip. T e cause of the inflammation is still a subject of great discussion. Proposed causes have included

- virus;
- trauma;
- allergy.

T e classic patient with transient synovitis of the hip is a 3- to 8-year-old boy with a history of acute unilateral hip pain associated with a limp but no history of an inciting episode. T ere is usually unilateral pain at the hip, knee, or thigh and the child may refuse to move the involved leg in any direction because of pain. T e hip is usually held in a position of flexion and external rotation so that the hip capsule is lax as much as possible, and the elevated intracapsular pressure is slightly relieved. If ROM can be examined, it is usually limited in abduction and internal rotation, although with gentle, slow ROM it is possible to obtain a full passive range of the hip.

T e intervention involves methods to alleviate the symptoms. T is includes rest, avoidance of weight bearing on the involved extremity, and anti-inflammatory therapy. Traction may be considered as a temporary means of relieving pressure on the joint. T e condition should be self-limiting unless there is a more serious condition such as septic arthritis or JRA present.[53]

Slipped Capital Femoral Epiphysis

SCFE is the most common disorder of the hip in adolescents. T e average age for girls to develop SCFEs is 12.1 ± 1 years and for boys 14.4 ± 1.3 years (Table 30-3).[54] T e term SCFE is actually a misnomer—it is characterized by a sudden or gradual anterior displacement of the femoral neck from the capital femoral epiphysis while the head remains in the acetabulum.[44] T e effects of coxa vara and valga demonstrate the principles underlying the mechanism of this condition. While the adult femur has a collum angle of approximately 125 degrees, the developing femur demonstrates considerably more coxa valga initially.[55] Failure of the epiphyseal plate occurs as a result of shear forces, which are forces applied parallel to the surface of the growth plate.[56,57] T e natural history of SCFE is that the capital femoral epiphysis eventually will fuse with the femoral neck at the end of adolescence. Two devastating complications that can adversely affect the result are avascular necrosis (osteonecrosis) and chondrolysis. T ese complications are uncommon sequelae in the untreated slip but are serious complications in the operative and nonoperative management of SCFE.[58] T e initiating traumatic episode may be as minimal as turning over in bed. Patients with chronic SCFE generally have a history of groin or medial thigh pain for months to years.[44] Approximately 45% will have knee or lower thigh pain as their initial symptom.[59] If the patient can walk, it is with difficulty and with a limp, often with external rotation of the involved foot. T e pain is reported as dull or aching, and there can also be a mild weakness of the leg. T e hip will often show decreased ROM, particularly of internal rotation, abduction, and flexion. On passive flexion of the hip, the patient will frequently externally rotate the leg. On the basis of the patient's history, physical examination, and radiographs, SCFE can be classified as a stable or unstable hip.[58,60] In the stable hip, weight bearing is possible with or without crutches. In the unstable hip, the patient presents more with fracture-like symptoms, with pain so severe that weight bearing is impossible.[1]

CLINICAL PEARL

Knowledge of SCFE and its manifestations will facilitate prompt referral by the clinician to an orthopaedic surgeon.

Intervention

T e goals of the intervention are relief of symptoms, containment of the femoral head, and restoration of ROM.[61] T e current method of choice is in situ surgical fixation. T e goal of containment is to maintain the sphericity of the femoral head. Other treatments are epiphysiodesis, osteotomy, salvage procedure, or spica cast. Complications from surgery include chondrolysis and/or necrosis of the femoral head, which increases the likelihood of significant joint degeneration in later years. Conservative intervention includes the use of traction for the relief of symptoms, at home or in the hospital, for periods ranging from 1 or 2 days to several weeks. Gait training postsurgery is initiated as soon as lower extremity strength and ROM are adequate for ambulation skills. T e weight-bearing status can vary but is usually nonweight bearing or touchdown weight bearing. Full weight bearing is permitted when the growth plate has fused (within approximately 3–4 months).

CLINICAL PEARL

Complications from surgery include chondrolysis, and/or necrosis of the femoral head, both of which increase the likelihood of significant joint degeneration in later years.

ROM exercises for the hip should be performed in all planes, but with particular emphasis on hip flexion, internal rotation, and abduction. Strengthening of the affected extremity is introduced when sufficient healing has occurred.

Scheuermann Disease

Scheuermann disease occurs in approximately 10% of the population, typically in pubescent athletes, and in males and females equally.[62] T e disease, considered to be a form of juvenile osteochondrosis of the spine, involves a defect to the ring apophysis where the vertebrae grow unevenly with respect to the sagittal plane resulting in an anterior angle that is often greater than the posterior angle.[63] T ese structural changes can cause the vertebral end plate to crack, thus making it possible for disk material to bulge into the vertebral body (Schmorl node). T e seventh and tenth thoracic vertebrae are most commonly affected.

| | | |

Clinical Findings

T e initial onset is typically asymptomatic but then progresses to lower and mid-level back pain, which can be severe and disabling. As the condition progresses, the patient may complain of an aching sensation in the upper spine. T e patient may report pain at the apex of the curve, which can be aggravated by physical activity and by long periods of standing or sitting. In addition, there may be observational evidence of an increased thoracic kyphosis and pain with thoracic extension and rotation, usually detected during a school physical or noted by the parents. Many patients often develop an excessive lordotic curve in the lumbar spine to compensate for the kyphotic curve above.

Intervention

T e intervention depends on the severity but typically involves postural education, a modification of the aggravating activity, exercise, or bracing. T e Schroth method, which originated in Germany as a treatment for scoliosis, is an exercise system which uses isometric and other exercises to strengthen or lengthen asymmetrical muscles in the spine with the goal to halt or reverse progression of abnormal spinal deviations. T e exercise program includes the stretching of the pectoralis major and minor muscles, and muscle strengthening exercises for the thoracic spine extensors (seated rotation and extension in lying exercises), and the scapular adductors.[64]

Spondylosis

Spondylolysis refers to a defect in the pars interarticularis, a stress fracture caused by repetitive extension and torsion of the spine.[65] Spondylolysis is common in patients involved with sports where repetitive extension and rotation of the lumbar spine occur frequently.[66] Bilateral spondylolysis at the same vertebral level can result in spondylolisthesis (see Chapter 28).[65]

Clinical Findings

T e patient typically presents with insidious onset of extension-related low back pain (LBP). Frequently, there is an associated reduction in hamstring flexibility. Occasionally, radiating pain, numbness, or weakness may be present.[65] A physical examination may reveal hyperlordosis, ipsilateral paraspinal muscle spasm, and adaptive shortening of the hamstrings.[65] T e ROM examination reveals pain with spinal extension. T e single-legged hyperextension test may localize the spondylolysis when standing on the ipsilateral leg (Fig. 30-8), although one study found this to be an insensitive test.[67] Radiographically, the anteroposterior view may identify anatomic variants or developmental effects, whereas the lateral view may demonstrate spondylolisthesis or a lytic lesion, and oblique views may demonstrate a stress reaction of the pars interarticularis, the pathognomic neck of the Scottie dog lesion.[65]

Intervention

T e conservative intervention includes activity modification with avoidance of any activities that cause pain. T e exercise program focuses on strengthening of the abdominal muscles, and hip flexor and hamstring stretches, while avoiding lumbar extension. Once the athlete becomes pain-free, activity can be gradually increased. Bracing is somewhat controversial. Indeed, one study illustrated that the best results were obtained with a period of rest from sport for 3 months, regardless of whether bracing was used.[68]

FIGURE 30-8 Single-legged hyperextension test.

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is a rare cause of anterior knee (it can also affect the elbow) pain in the young athlete. OCD of the knee will be discussed here. OCD is a joint disorder of unknown etiology in which fissures form in the articular cartilage and the underlying subchondral bone due to vascular deprivation (osteonecrosis). T e result is fragmentation (dissection) of both cartilage and bone, and the free movement of these osteochondral fragments within the joint space, causing pain and further damage.

If OCD occurs at the knee, it typically involves the weight-bearing portions of the medial and lateral femoral condyles, but can also occur in the trochlear groove, patella, and tibial plateau.[69]

Clinical Findings

Occasionally, pain may not be the most prominent symptom, but a catching sensation with joint motion may be the primary complaint if there is a loose body in the joint space. If the lesion is small, a painful arc is present during active and passive movement. Unfortunately, an effective clinical examination for OCD has yet to be identified and validated. T erefore, clinical diagnosis currently relies on plain radiographs and MRI.[70]

Intervention

When possible, nonoperative forms of management are attempted first. For OCD of the knee, this can include sports restriction, casting, bracing, and crutch walking (partial or nonweight bearing) and immobilization for the elbow are used. Approximately 50–67% of OCD of the knee found during childhood will heal within 6–18 months of nonoperative treatments.[71]

CLINICAL PEARL

If left untreated, juvenile OCD lesions can progress to adult forms of OCD, resulting in detachment or destruction of a portion of the joint surface and potentially leading to early osteoarthritis.[72] Unfortunately, most young patients are diagnosed with OCD a year or more after the onset of symptoms.[73] This is because nonspecific knee pain is the most common early symptom, so that OCD can be camouflaged among the many benign juvenile knee pain conditions, such as jumpers knee, Osgood–Schlatter, and patella femoral pain syndrome.[72] Thus, clinicians must be vigilant to identify OCD in young athletes and to initiate early treatment.

Surgical treatment varies widely and includes arthroscopic drilling of intact lesions, securing of cartilage flap lesions with pins or screws, drilling and replacement of cartilage plugs, stem cell transplantation, and joint replacement.

Although there are few evidence-based recommendations in the literature for postoperative rehabilitation following surgical intervention, the rehabilitation usually involves 4–12 weeks of some form of weight-bearing restriction and physical therapy to gradually increase ROM, maintain quadriceps function, and reduce joint swelling.[72] Isometric exercises, straight leg raises and cryotherapy are commonly used. T e exercises are progressed to include stationary bike and deep water running and then, once the patient achieves full ROM and weight bearing, muscle function is restored using closed chain exercises while protecting the joint's cartilage surface and underlying subchondral bone.

Osgood–Schlatter Disease

T e apophysis of growing bones differs from the epiphysis of skeletally immature bone in that the apophysis is an independent center of ossification that does not contribute to the longitudinal length of a long bone. T e apophysis does, however, contribute to the structure and form of mature long bone by serving as a site of tendinous or ligamentous attachment. Development of the tibial apophysis begins as a cartilaginous outgrowth, with secondary ossification centers appearing with subsequent progression to an epiphyseal phase when the proximal tibial physis closes and the tibial apophysis fuses to the tibia.[3] Osgood–Schlatter disease is a benign traction apophysitis that occurs at the tibial tubercle. It is a self-limiting knee condition that is one of the most common causes of knee pain in active and nonactive adolescents.[74] T e condition occurs in active boys and girls aged 11–18 coinciding with periods of growth spurts and occurs more frequently in boys than in girls.[75] During periods of rapid growth, stress from repetitive contractions of the quadriceps is transmitted through the patellar tendon onto a small portion of the partially developed tibial tuberosity. T is may result in multiple subacute avulsion fractures and inflammation of the tendon, and subsequent secondary heterotopic bone formation occurring in the tendon near its insertion.[75]

Clinical Findings

T e diagnosis of OS disease is relatively straightforward. T ere may or may not be a history of injury. Symptoms are typically unilateral, although 20–30% of cases can be bilateral in nature.[3] In the acute phase, the pain is severe and continuous in nature. T e pain occurs during activities such as running, jumping, squatting, and especially during kneeling, acute knee impact, and ascending or descending stairs. T ere is often a visible lump over the site. T e pain can be reproduced by extending the knee against resistance or stressing the quadriceps.

Intervention

T e intervention for OS disease is usually symptomatic, including anti-inflammatory measures, rest from the offending activity, and judicious stretching of the quadriceps and hamstrings (adaptively shortened hamstrings require increased quadriceps force to overcome the tight posterior structures). Bracing or enforced joint immobilization is rarely required, although the most persistent cases may require cast immobilization for 6–8 weeks.[75] T e progressive quadriceps stretching exercises begin with a bolster placed under the hips of the prone patient to place the muscle on slack at the hip joint. As tolerated, the bolster is removed to place the hip in extension for a complete stretch of the extensor mechanism as indicated. Rarely, individuals will require surgical excision of symptomatic ossicles or degenerated tendons if symptoms persistent into skeletal maturity.

Sever Disease (Calcaneal Apophysitis)

T e calcaneal apophysis serves as the attachment for the Achilles tendon superiorly and for the plantar fascia and the short muscles of the sole of the foot inferiorly.[76] Sever disease is a traction apophysitis of the growth center of the calcaneus that occurs at the insertion of the Achilles tendon and which is a common cause of heel pain in the athletically active child, with 61% of cases occurring bilaterally.[77] Sever disease typically affects children 8–13 years, with the peak incidence occurring at 11 years in young females and in 12 years in young males.[78–80] Young gymnasts, soccer players, and dancers are particularly susceptible to this condition because of their repetitive jumping or landing from a height.[81]

Clinical Findings

Sever disease is characterized by pain, point tenderness, and local inflammation at the posterior calcaneus near the insertion of the Achilles tendon. Patients with adaptively shortened calf muscles, internal tibial torsion, forefoot varus, a dorsally mobile first ray, weak dorsiflexors, and genu varus may be more susceptible to Sever disease.[3]

Intervention

T e intervention for Sever disease initially begins with a shortening of the gastrocnemius–soleus group using heel cups or heel wedges, and avoiding barefoot walking until becoming asymptomatic.[82] Stretching of the gastrocnemius–soleus, with the knee extended and the knee flexed, is only initiated after symptoms have subsided. When stretching in the weight-bearing position any rear foot to lower leg or forefoot to rear foot abnormality should be corrected before and during the exercise. Dorsiflexion strengthening exercises along with strengthening of the foot intrinsics may also help manage symptoms.[3]

Little Leaguer Elbow

Little Leaguer elbow is a common term, credited to Brogden and Cros,[83] for an avulsion lesion to the medial apophysis as a result of repetitive valgus stress. T e term has since been used to describe a variety of pathoanatomic lesions in the immature athlete, all of which relate to the frequency and mechanics of throwing. For example, overuse, high pitch counts, poor, and the type of pitch (curveball versus fastball) have all been cited as possible factors. Additional factors that influence its development include age, skeletal maturity, individual susceptibility, competitive level, and geographic location.[84] T e increasing popularity of competitive baseball among adolescents has been accompanied by a rise in the incidence of unique throwing-related injuries.[85] Each year, nearly 6 out of 10 young pitchers hurt their elbows.[86] T ese injuries can affect pitchers later in their lives making prevention extremely important. Repetitive throwing results in muscular and bony hypertrophic changes about the elbow, and can also result in ligament damage. T is has been reflected by an increase in the number of medial ulnar collateral ligament reconstruction ("Tommy John") procedures being performed on injured throwers.[87]

CLINICAL PEARL

A systematic review study reported that, despite much debate in the baseball community about the safety of the curveball, biomechanical and most epidemiologic studies do not demonstrate an increased risk of pain and/or injury when compared with the fastball.[88]

T e repetitive motions involved in the various phases of throwing place colossal strains on the elbow, particularly during the late cocking and acceleration phases (see "T e T rowing Athlete"). T ese strains can result in inflammation, scar formation, loose bodies, ligament sprains or ruptures, and the most serious conditions of osteochondritis or an avulsion fracture.[89,90] T e onset of Little Leaguer elbow can be insidious or sudden, with the latter typically secondary to fracture at the site of the lesion.

Clinical Findings

The child typically presents with pain and local tenderness on the medial side of the elbow. Physical findings depend on the severity but commonly include persistent elbow discomfort or stiffness due to aggravation by the injury. The clinician should seek out details, including[91]

- acute versus progressive injury;
- the intensity of symptoms;
- the duration of symptoms;
- throwing schedule;
- frequency of throwing;
- intensity;
- duration;
- types and proportion of pitches delivered;
- delivery style (sidearm versus overhead—the former is more injurious to the elbow);
- types and proportions of throws delivered (e.g., curve balls may be more deleterious than fastballs);
- rest periods employed;
- warm-up and cool-down regimens employed;
- phase the pain manifests in (e.g., early cocking, acceleration, and follow-through);
- restriction of motion;
- numbness. If the ulnar nerve is compromised, numbness in the ulnar distribution and a Tinel sign at the elbow may be present.
- locking or checkrein-type symptoms. A locking or "catching" sensation indicates a loose body.

Intervention

Management is conservative, involving rest and elimination of the offending activity. Lesions involving less than 0.5–1 cm of apophyseal separation are initially treated with the rest. T is is followed by a rehabilitation program similar to that described for medial epicondylitis except that resistance exercises are avoided until active range can be performed to full motion without pain (generally 2–3 weeks). T rowing is avoided for 6–12 weeks. If OCD is present, the joint needs protection for several months.[92] Any separation greater than 0.5–1 cm, sudden traumatic avulsions, or a failure to respond to conservative measures are indications for surgery. T e patient cannot return to pitching until full, and normal motion and strength has returned.

An interval long-toss throwing program is the staple of a return-to-activity phase.[93] T e interval throwing program starts skeletally mature players at a throwing distance of 45 ft (14 m) and progressively increases it to 180 ft (55 m).[94] T e use of proper mechanics is a critical aspect of the interval throwing program. To prevent future elbow disorders, young athletes should adhere to the rules of Little League, which limits the number of pitches per game, per week, and per season and the number of days of rest between pitching.[95] T e pitch count is the most important of these statistics.

Proximal Humeral Epiphysitis

T is condition often referred to as Little Leaguer shoulder, is also known as osteochondritis, epiphysitis, and epiphysiolysis of the proximal humeral epiphysis.[96] T e proximal humerus ossifies from four ossification centers: humeral head, greater

tuberosity, lesser tuberosity, and humeral shaft.[97] The ossification center for the humeral head is usually radiographically evident within the first year of life, whereas the greater tuberosity appears at age 3 and the lesser tuberosity at age 5.[96] The humeral head and tuberosity unite around age 6 to form a large proximal humeral epiphysis, which unites with the shaft around age 20.[96] Injury to the proximal humeral epiphysis usually occurs because of the two mechanisms in throwers: distraction and torsion.

Clinical Findings

Patients typically describe pain localized to the proximal humerus during both throwing and resisted shoulder strength testing. Palpation demonstrates local tenderness over the proximal humerus. The differential diagnosis of shoulder pain in adolescents throwers includes glenohumeral instability, rotator cuff tendinopathy, impingement, and proximal humerus physeal fracture.[96] Radiographs characteristically show widening of the proximal humeral physis.[96]

Intervention

Treatment includes cessation of throwing until the patient has pain-free ROM of the shoulder and radiographs return to normal, which may take up to 1 year.[98]

Pulled Elbow

The term pulled elbow or "nurse maid's elbow," refers to a common minor soft-tissue injury of the radiohumeral joint in children of preschool age. The incidence of this condition is 3% in children under the age of 8,[99] and it comprises 5.6% of all UE injuries involving children under the age of 10.[100,101] The left elbow is more commonly affected than the right,[102] and the disorder is more common in boys than in girls. The injury is caused by a sudden longitudinal traction force on the pronated wrist and extended elbow[103,104] resulting in the radial head slipping through the annular ligament, which causes the fibers of the annular ligament to become interposed between the radius and the capitellum of the humerus.[101,105]

These are the more common causes of pulled elbow[101]:

- The child is lifted by an adult from the ground by his hands.
- The child's forearm, wrist, or hand is being held firmly by a parent as the child attempts to walk away.
- A mother grabs the hand of a child to prevent a fall as the child wanders toward something potentially harmful.
- The young child is lifted by the hand from a lying or sitting position.
- The child is swung around by the hands several times during the course of play.

Clinical Findings

There is usually no obvious swelling or deformity, but the child presents with a painful and dangling arm, which hangs limply with the elbow extended and the forearm pronated.[101] The child is reluctant to use the arm and resists attempted supination of the forearm. The common sites of pain are (in order of occurrence) the forearm and wrist, the wrist alone, and the elbow alone.[105]

Intervention

The intervention of choice is manipulation.[101] Before attempting the manipulation, it is important to explain the procedure to the parents and to win the confidence of the child, by gently supporting the injured arm before manipulation. During the procedure, the clinician holds the child's wrist with one hand while the other hand supports the elbow and palpates the radial head. The child's attention is diverted, and the forearm is forcibly supinated with one quick motion, together with the application of downward pressure on the radial head. A click in the region of the radial head (palpable and sometimes audible) is indicative of a successful reduction. Sometimes, the forearm has to be pronated after forcible supination to reduce the pulled elbow. The click results from the release of the trapped annular ligament. Soon after the manipulation, the child typically begins to use the arm again, but sometimes there can be a delay of a day or two. In such cases, a sling can be used to both give comfort and protect the arm from a recurrence.

The parents should be advised to avoid a longitudinal traction strain on the child's arm by not pulling on the hands or wrists.[101]

Distal Radial Epiphysitis

Radial physes appear at 12–18 months and fuse by 15–18 years.[106] Distal radial apophyseal injuries are most common in male and female gymnasts but occasionally happen in other sports.

Clinical Findings

The patient typically describes a gradual onset of wrist pain made worse by weight-bearing activities while the wrist is in extension. Physical examination often reveals normal ROM but swelling of the distal radius. Tenderness is frequently found over the posterior (dorsal)-radial growth plate but may also be elicited on the anterior (volar)-radial physis as well. Radiographic findings depend on the stage of the disease. Although these injuries are usually confined to the distal forearm, the carpus can sometimes be involved.

Intervention

Time to healing is dependent on the stage of the disease in the radiographic findings. When radiographs are negative, 4 weeks of rest usually allow for healing and return to activities. In other cases, immobilization in a cast is the mainstay of treatment.

The Aging Athlete

The field of geriatrics continues to gain attention due to the rapid growth of this segment of the population and its predicted future socioeconomic impact. It is therefore inevitable that future rehabilitation professionals will see an increase in the number of elderly individuals seeking services for the management of both acute and chronic conditions that can negatively impact active life expectancy or the number of years that an individual may expect to be independent in ADLs.[107,108] Therefore, rehabilitation, with its potential to

restore function, prolong independence, and improve the QoL, can be extremely important in this population.

The Aging Process

Aging is the accumulation of diverse adverse changes that increase the risk of death.[109] T e rate of aging, that is, the rate at which aging changes occur, typically varies from individual to individual, resulting in differences in the impact of aging on function.[109] T e aging process can be attributed to a combination of development, genetic defects, the environment, social and recreational habits, and disease, some or all of which are responsible for sequential alterations that accompany advancing age and the progressive probability of experiencing a chronic debilitating disease.[109] T is increase in the incidence of chronic conditions with advancing age occurs largely because this period in life is often accompanied by a deterioration in health and a subsequent loss of independence. Complicating matters is the presence of comorbidities at this time of life, such as cardiovascular disorders, osteoporosis, arthritis, and diabetes, which increase the vulnerability of the geriatric patient.

CLINICAL PEARL

- Geriatrics is the branch of medicine that focuses on health promotion and the prevention and treatment of disease and disability in later life.
- Gerontology is the study of the aging process and the science related to the care of the elderly.
- Senescence can be defined as the combination of processes of deterioration which follow the period of development of an organism.

As previously mentioned, coexisting pathologic processes or comorbidities can exacerbate the effects of other conditions and result in greater functional limitations and disability. T roughout youth and early adulthood, the body has a number of physiologic reserves from which to draw upon when faced with physical challenges and injury, without a loss of functional abilities. However, older individuals have fewer of these system redundancies due to a gradual decline of health and increased the incidence of injury and disease.[110] Without these physiologic reserves, an older individual is more susceptible to functional limitations and disability, resulting in frailty—the opposite end of the spectrum from successful aging.[110]

Changes Associated with the Aging Athlete

A number of changes can negatively impact the performance of the aging athlete, including cardiovascular, and neuromusculoskeletal changes.

- Cardiovascular. T e geriatric patient who has been given a prescription for physical therapy may not have been physically active for some time, and his or her level of fitness may have declined considerably. Age-related changes of the heart and blood vessels, which can either be mitigated or exacerbated by activity level, typically result in reduced capacity for oxygen transport at rest and in response to situations imposing an increase in metabolic demand for oxygen.[110] In addition, maximal oxygen consumption decreases 5–15% per decade after the age of 25 years.[111] As a result, at submaximal exercise, cardiac output and stroke volume are lower in older adults at the same absolute work rates, while BPs tend to be higher.[111] It is very important that elderly patients have a physician's evaluation of their cardiovascular status before engaging in a rehabilitation program. In addition, the patient should be carefully monitored for their cardiovascular response and tolerance to exercise during their rehabilitation sessions. Heart rate, BP, and rate of perceived exertion (RPE) should be assessed before, during, and after exercise, and the physician should be notified of any abnormal or unusual findings. In addition to the normal aging changes, a number of complications can occur in the elderly[112]:
  - Acute inactivity, such as that which occurs with hospitalization, can significantly reduce VO_{2max} and increase blood viscosity and venous status, which increases the risk of thromboembolic disease. Immobility in the elderly can be a common pathway for a host of diseases and further disability. T e chronically ill, aged, or disabled are particularly susceptible.
  - Cardiac diseases, such as coronary artery disease (CAD) and the sequelae of myocardial infarction (MI) and cardiomyopathy:
    a. CAD is a complex disease of the cardiac arteries resulting in ischemia to the myocardium. T e clinical symptoms of CAD include angina (an ache, pressure, pain, or other discomfort in the chest, arms, back, or neck), shortness of breath, a decrease in activity tolerance, or palpitations.
    b. MI is a development of myocardial necrosis caused by an imbalance between the oxygen supply and demand of the myocardium, typically resulting from plaque rupture with thrombus formation in a coronary vessel, and subsequent acute reduction of blood supply to a portion of the myocardium. T is patient population is a much greater risk of an adverse event during exercise, and, therefore, careful consideration, screening, and monitoring must occur to ensure safety with a rehabilitation program.
  - Left ventricular hypertrophy, left atrial enlargement, aortic root dilatation, arrhythmias, and ischemic heart disease.
  - Hypertension, which may be either essential or secondary, can have a number of negative impacts.
- Neuromusculoskeletal. T e neuromusculoskeletal changes associated with aging affect all of the soft tissues and bone and many parts of the nervous system. Even healthy and active elderly individuals experience functional loss due to remodeling in the motor system, including muscle cells and upper and lower motor neurons.[113] Musculoskeletal impairments are some of the most prevalent and symptomatic health problems of the middle and old age.[114] and result in a gradual loss of strength, motion, and increasing pain. T ese changes prevent elderly individuals from participating in regular

physical activity, optimum mobility and, in some cases, reduce independence.[110]

Sarcopenia, often defined as the age-related decrease in lean body mass, has become a topic of significant investigation.[115] Although a natural phenomenon, some of the changes associated with sarcopenia are associated with a decrease in physical activity. There is a spectrum of changes in aging muscle, some of which are normal (age-related sarcopenia) and some of which are not (e.g., cancer-related anorexia and cachexia syndrome[]).[115] Age-related sarcopenia tends to begin at about age 60 in some muscles, and quite inexorably in others.[116] If left unchecked, muscle size can decrease an average of 30–40% over one's lifetime, affecting the lower extremities more than the upper extremities.[117] Type I muscle fibers, which are slow contracting, low tension output fibers that are highly resistant to fatigue and are capable of metabolizing fat for energy expenditure (see Chapter 1) tend to be less impacted than type II muscle fibers. In fact, their overall percentage when compared to type II muscle fibers increases. Type II muscle fibers, which are used primarily in activities requiring more power are not stimulated by normal ADLs often disappear at a faster rate than Type I fibers. Indeed, Type II fibers decrease from an average of 60% of total muscle fiber type in sedentary young men to below 30% after the age of 80 years.[118]

CLINICAL PEARL

According to the 2010 European Working Group on Sarcopenia in Older People, there are three stages of the muscle aging process[119]:

- Presarcopenia is simply a loss of muscle mass.
- Sarcopenia is muscle loss that occurs in conjunction with loss of strength or physical performance.
- Severe sarcopenia occurs when muscle loss is present with both strength and physical performance loss.

Muscle is at the end of the chain of events in movement, so virtually every step involved from oxygenating the blood to the delivery of oxygen to working muscles may contribute in some manner to sarcopenia.[115] Fortunately, skeletal muscle demonstrates a high degree of plasticity and is able to adapt to its demands throughout life. Thus, strength can be enhanced in adults, and quite substantially in the sedentary using customized exercise programs. Given the predominant loss of Type II muscle fibers, the focus on this age group should be the prescription of exercises that develop coordinated movements, the speed of movement, strength, and power.

CLINICAL PEARL

One pharmacological direction under investigation to prevent sarcopenia is the development of selective androgen receptor modulators (SARMs), which are a synthetic group of compounds that bind to specific areas of androgen receptors and are designed to encourage muscle growth while at the same time preventing some of the unwanted aspects of hormone therapy.[115,120]

In addition to the age-related changes in muscle, aging changes also occur in the biology, healing capacity, and biomechanical function of tendons and ligaments.

Tendons. There are structural changes in tendon such as collagen disorganization and decreased collagen content with aging, which can alter the biomechanical response of tendon tissue.[121] The most common clinical tendon problems for the aging population are in the rotator cuff, Achilles, lateral elbow epicondyle, quadriceps, and patella tendon.[122]

Ligaments. With aging, collagen fiber disorientation occurs that results in decreased linear stiffness and ultimate load.

CLINICAL PEARL

Two musculoskeletal conditions that can severely impact function in the aging athlete are osteoporosis (see Chapter 5) and osteoarthritis.

Shoulder. The normal high degree of mobility associated with the shoulder declines not only with age but with long-term sports participation.[123] A number of musculoskeletal conditions are common in the aging shoulder including the following:

- Rotator cuff pathology. Rotator cuff pathology in this age range runs the gamut from tendinitis to massive tear. Partial thickness tears are quite common. A 2010 in vivo study,[124] evaluating the vascularity of rotator cuff tears using ultrasound, showed that there was a significant decrease in blood flow in the intratendon this region in elderly subjects compared with younger subjects but no differences in the bursal blood flow suggesting age-related decrease in intratendinous vascularity.[122]
- Adhesive capsulitis. This is condition is described in detail in Chapter 16. For the aging athlete, conservative management is a reasonable, evidence-based approach with one study[125] finding that physical therapy with the steroid injections significantly better than that without at 3-month follow-up, although both groups were similar at 1 year.
- Osteoarthritis. While osteoarthritis of the shoulder is not as common as it is in the knee and hip, it is not uncommon, and can be debilitating if added to the myriad of pain generators in the biceps, acromioclavicular joint, and subacromial space.[126] However, for the older recreational patient who is able to limit activity, total shoulder arthroplasty provides excellent long-term survival rates and return to sport is high.[127]

CLINICAL PEARL

Fractures, which can have a significant impact on morbidity, mortality, and functional dependence, commonly occur among the elderly. Such fractures include pathologic fractures, proximal femur fractures, proximal humerus fractures, distal radius fractures, compression fractures of the spine, and stress fractures.

[]Cachexia is a pathological process that involves increases in muscle protein synthesis and degradation, basal metabolic rate and energy expenditure, inflammation, and insulin resistance which results in a loss of muscle and fat mass.

The history and physical examination of the aging athlete must differentiate between the effects of aging, inactivity, and disease on the underlying impairments and functional limitations that result in movement dysfunction.[128] For example, mild impairments in ROM may be due to increased stiffness associated with aging that occurs in the tendinous or ligamentous structures around a joint, or it could be due to acute immobilization, or chronic inactivity and reduced demands on a particular joint for full ROM.[112]

The Female Athlete

Both male and female children are basically equal in physical condition and have the same strength before puberty. After puberty (Table 30-2), females aged 11–12 years are 90% as strong as their male counterparts versus 85% as strong at ages 13–14, and 75% at ages 15–16 years.[129]

ACL Injury

Although skeletal muscle physiology in men and women does not differ significantly—the actual number of muscle fibers is similar between genders—men do appear to demonstrate larger absolute strength gains due to a larger cross-sectional muscle fiber size. When comparing strength to lean body mass or cross-sectional area, women are about equal to men and are equally capable of developing strength relative to total muscle mass. However, differences in anatomy make the female more prone to certain injuries. A variety of studies have reported that female athletes are six to eight times more likely to sustain an ACL injury than their male counterparts, and most of these injuries occur without contact.[130] Theories about the higher rates of ACL injury in women have centered on the following[131]:

- Anatomic alignment and structural differences. These include the differences in pelvic width and the tibiofemoral angle between males and females, which can affect the entire lower extremity.[132] For example, women demonstrate greater amounts of static external knee rotation, greater active internal hip rotation, and increased hip width when normalized to femoral length than men, resulting in a number of structural combinations.[133] In addition, the magnitude of the quadriceps femoris angle (Q-angle) and the width of the femoral notch are thought to be anatomic factors that have contributed to the disparity of ACL injury rates between males and females.[131] Hypothetically, a larger Q-angle increases the lateral pull of the quadriceps femoris muscle on the patella placing medial stress on the knee,[132] decreasing the effectiveness of the quadriceps as a knee extensor and diminishing the ability of the hamstrings to exert their protective influence on the ACL.
- Femoral notch. A narrow intercondylar notch appears to increase the potential for ACL ruptures.[134] In a cadaver study, Norwood and Cross[135] showed that the ACL impinges on the anterior intercondylar notch with the knee in full extension.[131] The shape of the femoral notch varies with gender and may contribute to the incidence of ACL injury.[136] A small, A-shaped notch may be a sign of a congenitally smaller ACL.[136]
- Joint laxity. Joint laxity tends to be greater in women than in men,[137–139] although the correlation between ligamentous laxity and injury is not clear.
- Hormonal influence. Hormones, especially estrogen, estradiol, and relaxin, may be involved indirectly in increased ACL injury in females.[140,141]
- ACL size. Females typically have a smaller ACL than males, which would tend to enhance the risk of tissue failure.[142]
- Muscular strength and muscular activation patterns. Several studies have demonstrated that women have significantly less muscle strength in the quadriceps and hamstrings compared with men, even when muscle strength is normalized for body weight.[139,143–146] Approximately 30% of all ACL injuries are classified as contact injuries, and the remaining 70% are not related to direct contact and are therefore classified as noncontact.[147,148] The most common noncontact of ACL injury in females are as follows[147,148]:
  - Planting and cutting
  - Straight knee landings
  - One-step stop with the knee hyperextended
  - Sudden deceleration

While landing injuries to the ACL are common in both males and females, male athletes appear to employ different mechanisms to compensate for high landing forces than females, resulting in a decrease in both varus and valgus laxity of the knee during the landing.[149–152] Females have some unique characteristics that may predispose them to ACL injury, including increased genu valgum, a poor hamstring-quadriceps strength ratio, running and landing on a more extended knee, quadriceps-dominant knee posture, hormonal changes, and hip/core weakness.[153] Because a common mechanism of noncontact ACL injury is valgus stress with rotation at the knee, it is important that the female athlete learns to control this valgus moment[154,155] using exercises designed to control this moment including front step downs, lateral step downs with resistance, and squats with resistance around the distal femur.[153] In addition, the following should be emphasized[153]:

- Patient education on optimal knee alignment (keeping the knee over the second toe);
- Exercises to train the patient to stabilize the knee through coactivation of the quadriceps and hamstrings, including tilt board balance exercises while performing a throw and catch;
- Dynamic stabilization drills to teach the patient to land with the knee flexed to approximately 30 degrees to promote better alignment and activation of the quadriceps and hamstrings; and
- Exercises to train the hip extensors, external rotators, abductors, and core stabilizers while emphasizing a flexed-knee posture while running, cutting, and jumping.

Pregnancy

Pregnancy is a state of wellness that spans approximately 40 weeks from conception to delivery. A number of physiologic

changes occur during pregnancy and the postpartum period within the various body systems that can present the clinician with some unique challenges. Given the number of physiologic changes during pregnancy and the postpartum period within the various body systems, the extent of the physical therapy intervention will depend on the findings of the examination.

Endocrine System

Changes that occur in the endocrine system include but are not limited to the following:

- Enlargement of the adrenal, thyroid, parathyroid, and pituitary glands.
- An increase in hormonal levels to support the pregnancy and the placenta and in preparation for labor. For example, a female hormone (relaxin) is released that assists in the softening of the pubic symphysis so that during delivery, the female pelvis can expand sufficiently to allow birth. Unfortunately, the hormone is not specific to this region and produces greater laxity in all joints.[156,157] T is can result in an increased susceptibility to musculoskeletal injury.

Musculoskeletal System

Pregnancy can produce a number of changes within the musculoskeletal system:

- T e abdominal muscles are stretched to the point of the elastic limit and become weakened.
- T e development of relative ligamentous laxity, both capsular and extracapsular.
- T e rib cage circumference increases resulting in a natural state of hyperventilation to meet the oxygen demands.
- Pelvic floor muscle weakness. Due to the increased weight and pressure directly over these muscles, the muscles of the pelvic floor become stretched and compromised during labor—the pelvic floor drops as much as 2.5 cm (1 in) as a result of pregnancy.[158] On occasions, the pelvic floor musculature, may also be torn or incised during the birth process. T is can lead to a number of dysfunctions including pain, prolapse, urinary or fecal incontinence, and hypertonus. Interventions include neuromuscular reeducation, patient education, biofeedback with instrumentation, and specific exercises [see "Pelvic Floor Dysfunction"].
- Postural compensations to maintain stability and balance. T ese changes are related to the weight of growing breasts, and the uterus and fetus, resulting in a shift in the woman's center of gravity in an anterior and superior direction. Specific postural changes include an increased lumbar lordosis, an increased thoracic kyphosis with scapular retraction and rounded shoulders, and an increased cervical lordosis and forward head. T ese changes in posture can become habitual postpartum.
- Changes in gait. Since the weight increases, and the body mass is redistributed, compensations are necessary to maintain balance and perform even simple functions such as walking. In advanced pregnancy, the patient develops a wider base of support and increased external rotation at the hips and demonstrates increased difficulty with walking, stair climbing, and rapid changes in position.[159]

Common diagnoses associated with some of the above includes:

- Symphysis pubis dysfunction (SPD).[160–163] T is disorder can occur as a result of trauma during vaginal delivery. SPD should always be considered when treating patients in the postpartum period who are experiencing suprapubic, sacroiliac, or thigh pain (see Chapter 29).

CLINICAL PEARL

Symphysis pubic dysfunction (SPD) should always be considered when treating patients in the postpartum period who are experiencing suprapubic, sacroiliac, or thigh pain.

- Lumbopelvic pain.[164–168] Pregnancy-related lumbar pelvic pain during pregnancy, defined as pregnancy-related LBP and/or pregnancy-related pelvic girdle pain (PGP), is a complex problem, with both a physical and psychological burden.[169] T e prevalence is reported to range from 24% to 90%, largely in part because of the lack of a clear definition and classification of the condition.[170–173] Back pain after delivery has been reported to be at 67% while 37% experience back pain 18 months postpartum.[151] Back pain tends to begin early in pregnancy, with a 25% prevalence at 12 weeks.[149] T e most common location of back pain in pregnant women[174] is the sacroiliac region. T e cause of back pain during the childbearing year is thought to be related to the mechanical and hormonal changes. Several studies indicate that women with severe LBP during pregnancy are at extremely high risk for developing new episodes of severe LBP during a subsequent pregnancy as well as later in life.[168–170] It is not clear whether the LBP is the result of the shift in the center of gravity, the associated postural changes, or changes to an intervertebral disk due to the release of relaxin. However, disk herniations are no more common during pregnancy than at other times. It is also important to consider systemic causes for LBP in this population. Kidney or urinary tract infections can both cause LBP. A 2014 systematic review of the literature by Van Benten et al.[169] found that all of the included studies on exercise therapy, and most of the studies on interventions combined with patient education, reported a positive effect on pain, disability, and/or sick leave.

CLINICAL PEARL

It is worth remembering that complaints of LBP in this population may be because of a kidney or urinary tract infection.

- Peripartum posterior pelvic pain (PPPP). PPPP can be defined as unexplained and undiagnosed pain in the pelvic region (with or without radiation) that started

during pregnancy or within 3 weeks after delivery. About 49% of pregnant women experiences some type of pelvic pain,[171] with 33% of these women experiencing severe pain.[175–177] T e pain is typically experienced in the lumbar region and over the sacroiliac joints (with no findings suggesting nerve root involvement). Although the etiology of PPPP is unknown, it has been linked to the many physiological adaptations that occur in preparation for childbirth. T e previously mentioned change in the center of gravity leads to a change in the degree of lordosis of the spine, which in turn affects the paraspinal musculature. In addition, the hormonal changes that occur during pregnancy may cause an imbalance between the ligaments, muscles, and joints in the posterior aspect of the pelvis.[159] Although a systematic review[160] of the literature investigating the effectiveness of physical therapy interventions in the treatment of PPPP and LBP found scant evidence to support the use of exercise or mobilization in this patient population, exercise is thought to be beneficial in the post-partum period. In addition, the patient should be given posture/body mechanics advice using the suggestions listed for SPD.

- Coccydynia.[178–182] Pain in and around the region of the coccyx, especially with sitting, is relatively common postpartum. Seating adaptations such as a donut cushion can be prescribed to lessen the weight on the coccyx and to support the lumbar lordosis. If symptoms persist for more than a few weeks, the displaced coccyx can often be corrected manually (see Chapter 29).
- Diastasis recti abdominis (DRA). A DRA is known as a split between the two rectus abdominis (RA) muscles to the extent that the linea alba may split under strain. T e size of the DRA can vary from 2–3 to 12–20 cm in width and from 12 to 15 cm to the entire length of the recti muscles. It has not been determined whether the separation is a true tear or a relaxation of the tissue. A DRA is common in pre- and postpartum women. Predisposing factors for a DRA in women include obesity, a narrow pelvis, multipara, multiple births, excess uterine fluid, large babies, and weak abdominals prior to pregnancy. T e separation may develop during the second and third trimesters of pregnancy, during second stage labor, and during the postpartum period. It is believed that a DRA may hinder the abdominal wall function related to posture, trunk stability and strength, respiration, visceral support, diminished pelvic floor facilitation, and delivery of the fetus. An umbilical hernia may result as well. T e DRA is believed to contribute to chronic pelvic and LBP.

  Criteria have been established for determining a DRA. T e patient is positioned in the hook lying position. T e clinician palpates with fingers horizontally, at the umbilicus and 2 in above and below the umbilicus, and the patient is asked to raise their head and shoulders while reaching toward their feet. Any separation will be palpable, and a wide ridge of bulging tissue may actually be visible. If a DRA of 1–2 fingers width (1–2 cm) is present, this is considered within normal limits.[174] Any separation greater than two-finger wide constitutes a DRA, and, therefore, restrictions on abdominal exercise prescription should apply. However, it is worth remembering that the interrater reliability for measuring a DRA by manually inserting the fingers into the gap has been considered poor.

  Electromyography studies of the RA and external oblique have been done on primiparas women during the pre- and postpartum stages.[183] It was found that the abdominals generated the same muscle activity throughout the pregnancy; however, the ability to stabilize the pelvis against resistance decreased as the pregnancy progressed and continued to remain low postpartum.[183] It was observed that the RA length, angles of insertion, and DRA were significant between 18 and 30 weeks, with further structural changes between 26 and 38 weeks; therefore, the ability to produce torque may be reduced.[183] T e decreased functional deficits were present up to 8 weeks postpartum, in conjunction with the incomplete resolution of the structural adaptations of RA. It is essential that these functional and structural deficits be addressed with pre- and postpartum women.[183]

  Ostgaard[184] found that individualized exercise and education were significantly helpful in reducing back pain during the 8-week postpartum phase; however, no differences in back pain were found during pregnancy. Weekly physical exercise before pregnancy was found to reduce the risk for back pain during pregnancy. Diagnostic ultrasound has been used to determine exercise effectiveness on decreasing the amount of a DRA.[185] It was determined that when performing a curl-up, the RA contraction significantly reduced the DRA compared to other movements studied.[185] T e additional movements tested were curl-up with rotation to left and right, posterior pelvic tilt, and abdominal hollowing.[185] T ere was no evaluation of a possible relationship between DRA and back pain. Although it was not a controlled variable in this study, exercise prior to pregnancy may reduce the risk of a DRA.

  According to Noble,[186] exercises for the abdominals to prevent, decrease, and/or eliminate a DRA should be prescribed. Proper exercise intensity is essential, and intervention should occur as soon as possible. If exercise has not been started before or during pregnancy, basic abdominal isometrics with exhalation should begin within 24 hours of delivery.[187] On postpartum day 3, the abdominals should be evaluated for a DRA.[187] Curl-ups with the abdominal isometric and the crossover of the upper extremities for additional support can be done.[186] If the DRA is greater than three fingers width (3 cm), there are restrictions on curl-ups and leg-lowering exercises.[187] Curl-ups of the head only, with the abdominal isometric and the crossover of the upper extremities, should be prescribed.[187] Advancement of the exercises should not occur until the DRA has decreased.[187] Many times women will actually increase the DRA during the postpartum phase with abdominal exercises that are too aggressive for the individual.[187] T e patient should be instructed in self-monitoring of her DRA.[187] A diastasis correction exercise can be performed to maintain alignment and discourage further separation. T e exercise is performed in the supine hook-lying position (if tolerated and not contraindicated). With the arms crisscrossed over the abdomen, the patient manually approximates the recti muscles toward midline, performs a posterior pelvic tilt, and slowly exhales while lifting her head so that the scapulae clear the surface.[166,175] In addition, the

patient can perform any exercise that does not stress the sacroiliac joint or increase intraabdominal pressure including leg sliding (see Chapter 28), abdominal isometrics with lower extremity movements, supine bridging (see Chapter 28), quadruped leg raising (see Chapter 28), modified squats (see Chapter 28), and posterior pelvic tilts (see Chapter 28) while using hands to support the abdominal wall.[174] Maintaining the stability of the pelvis and decreasing the DRA are the goals for exercise progression.[187] Educating the patient about proper body mechanics and posture is necessary to prevent undue stress on the back and the DRA during the postpartum phase.[187]

Neurologic

Swelling and increased fluid volume can cause symptoms of thoracic outlet syndrome due to compression of the brachial plexus, carpal tunnel syndrome due to median nerve compression, or meralgia paresthetica, which is compression of the lateral (femoral) cutaneous nerve of the thigh (see Chapter 3).[188–190]

Pregnancy-related depression and postpartum depression has been documented to occur in 5–20% of all postpartum mothers,[191–193] but can also occur in fathers.[194] T ese disorders can range from a mild "postpartum blues," which occurs from 1 to 5 days after birth and lasts for only a few days, to the more severe forms that include postpartum depression and postpartum psychosis, which require medical or social intervention.[195–197]

Gastrointestinal

Nausea and vomiting may occur in early pregnancy and are generally confined to the first 16 weeks of pregnancy but occasionally remain throughout the entire 10 lunar months (hyperemesis gravidarum).[195,198–201] T e causes of hyperemesis gravidarum are largely unknown.

Cardiopulmonary System

To meet the increased metabolic demands of the mother and fetus, various pregnancy-induced changes occur in the cardiovascular system. T ese changes include the following:

- A predominance of costal versus abdominal breathing as the diaphragm elevates with a widening of the thoracic cage.
- Mild increases in oxygen consumption due to increased respiratory center sensitivity and drive.[202] Even with mild exercise there is a greater than normal increase in respiratory frequency and oxygen consumption to meet the greater oxygen demand.[202] However, pregnant women demonstrate decreased respiratory frequency and maximal oxygen consumption as exercise increases to moderate and maximal levels.[202]
- A compensated respiratory alkalosis.[203]
- A low expiratory reserve volume.[202]
- Increased blood volume: T e total increase is between 35% and 50% (1.5–2 L). T e increased blood volume serves two purposes[204,205]
  - To facilitates maternal and fetal exchanges of respiratory gases, nutrients, and metabolites.
  - To reduce the impact of maternal blood loss at delivery.
- Increased plasma volume is relatively greater than that of red cell mass resulting in hemodilution and a decrease in hemoglobin.[204,206,207]
- Increased cardiac output. T is increases to a similar degree as the blood volume (30–60%).[204, 205]

CLINICAL PEARL

Hypertensive disorders complicating pregnancy are the most common medical risk factor responsible for maternal morbidity and death related to pregnancy.[195] Although BP decreases early in the first trimester, it gradually rises from mid pregnancy.

Changes in BP during pregnancy include:

- Systemic arterial pressure should not increase during normal gestation.
- Pulmonary arterial pressure also maintains a constant level.
- Hypotension develops more readily and more markedly.
- Central venous and brachial venous pressures remain unchanged during pregnancy.

During pregnancy, a condition called supine hypotension (also known as inferior vena cava syndrome), manifested by a decrease in BP, may develop in the supine position, especially after the first trimester. T e drop in BP is thought to be caused by the occlusion of the aorta and inferior vena cava by the increased weight and size of the uterus as spontaneous recovery usually occurs upon a change of maternal position. However, although a change in position is necessary, patients should not be allowed to stand up quickly to avoid another condition related to a decrease in BP; orthostatic hypotension. Signs and symptoms of this condition run the gamut from a headache, bradycardia, dizziness, and shortness of breath to numbness in extremities, nausea and vomiting, and syncope (fainting). Ideally, the time spent in supine should be limited to approximately 5 minutes. Alternative positions include side lying (best position for minimizing compression), supine reclined, or supine with a small wedge under the right hip.

Metabolic System

T e metabolic rate increases during both exercise and pregnancy. T us, an additional intake of 300 cals per day is needed to meet the basic metabolic needs of pregnancy. Fetoplacental metabolism generates additional heat, which maintains fetal temperature at 0.5–1°C (0.9–1.8°F) above maternal levels.[208–210] Because of the increased demand for tissue growth, insulin is elevated from plasma expansion and blood glucose is reduced for a given insulin load. Fats and minerals are stored for maternal use.

Gestational diabetes is defined as carbohydrate intolerance of variable severity, with onset or first recognition during

pregnancy. After the birth, blood sugars usually return to normal levels; however, frank diabetes often develops later in life. Typical causes include

- genetic predisposition;
- high-risk populations include people of Aboriginal, Hispanic, Asian or African descent;
- a family history of diabetes, gestational diabetes, or glucose intolerance;
- increased tissue resistance to insulin during pregnancy, due to increased levels of estrogen and progesterone.

Current risk factors include

- maternal obesity (> 20% above ideal weight). T e recommended weight gain during pregnancy is 25–27 lb.[211]
- low level of high-density lipoprotein cholesterol (< 0.9 mmol/L) or elevated fasting level of triglycerides (> 2.8 mmol/L),
- hypertension or preeclampsia (risk for gestational diabetes is increased to 10–15% when hypertension is diagnosed),
- maternal age > 25 years.

Most individuals with gestational diabetes are asymptomatic. However, subjectively the patient may complain of

- polydipsia,
- polyuria,
- polyphagia,
- weight loss.

Renal and Urologic Systems

Anatomic and hormonal changes during pregnancy place the pregnant woman at risk for both lower and upper urinary tract infections and for urinary incontinence.[195] T e size of the uterus increases fivefold, and 20 times in weight by the end of pregnancy. In addition, the ureter enters the bladder at a perpendicular angle because of the uterine enlargement and this can result in a reflux of urine out of the bladder and back into the ureter, which can result in urinary tract infections. As the fetus grows, stress on the mother's bladder can increases. T is can result in urinary incontinence (refer to "Urinary Incontinence").

Exercise Prescription

T e goals of therapeutic exercise during pregnancy are to improve muscle balance and posture, help provide support of the growing uterus, stabilization of the trunk and pelvis, and maintenance of function for more rapid recovery after delivery.[195] Contraindications to exercise include the following[212]:

- An incompetent cervix (early dilation of the cervix before pregnancy is full-term)
- Vaginal bleeding (especially second or third trimester)
- Placenta previa (the placenta is located on the uterus in a position where it may detach before the baby is delivered)
- Multiple gestations with risk of premature labor
- Pregnancy-induced hypertension
- Premature labor (labor beginning before the 37th week of pregnancy)
- Maternal heart disease
- Maternal type I diabetes
- Intrauterine growth retardation[212]

Even without these conditions, the patient requires permission from her physician before beginning an exercise program. Some precautions should be observed during exercise.[213–220]

Exercise programs for high-risk pregnancies should be individually established based on diagnosis, limitations, physical therapy examination and evaluation, and in consultation with the physician. Exercises for the pelvic floor are described in "Pelvic Floor Dysfunction."

Objective data on the impact of exercise on the mother, the fetus, and the course of pregnancy are limited, and results of the few studies in humans are often equivocal or contradictory.[218] No human research has conclusively proven a detrimental feature response to mild, moderate, or high-intensity exercise during pregnancy. However, as both exercise and pregnancy are associated with a high demand for energy, the competing energy demands of the exercising mother and the growing fetus raise the theoretic concern that excessive exercise might adversely affect fetal development.[195] T erefore, theoretically, because of the physiologic changes associated with pregnancy, as well as the hemodynamic response to exercise, some precautions should be observed during exercise (Table 30-4).[213–220] Warning signs associated with exercise during pregnancy include pain, vaginal bleeding, tachycardia, dyspnea, uterine contractions, and chest pain.[221]

Adjunctive Interventions. Modalities that increase body heat (hot packs, ultrasound, shortwave or microwave diathermy) should be used with caution, especially over the abdomen or uterus. Except for the use of transcutaneous electrical stimulation during labor and delivery, electrical stimulation is contraindicated during pregnancy.

Pelvic Floor Dysfunction

Pelvic floor dysfunction (PFD) may result in a group of clinical disorders that includes urinary incontinence, anal incontinence, pelvic organ prolapse, sensory and emptying abnormalities of the lower urinary tract, defecatory dysfunction, sexual dysfunction, and several chronic pain syndromes.[222] Of these, the physical therapist most commonly encounters patients who require treatment for chronic pain syndromes (see Chapter 5), and urinary incontinence, of which the latter tend to be female.[223–227]

Urinary incontinence includes the various types of incontinence: stress incontinence (a loss of bladder control associated with increased abdominal pressure that occurs during coughing or exercise), urge incontinence (a sudden urge to urinate), or mixed incontinence (a combination of stress and urge incontinence).[228] T e contributing factors to urinary incontinence can be a weakness or damage to numerous pelvic floor structures, including fascial structures, nerves, and the pelvic floor musculature. T e pelvic floor muscles demonstrate abnormalities of muscle activation and

TABLE 30-4	Exercise Precautions During Pregnancy
Exercise intensity	Exercise programs for high-risk pregnancies should be individually established on the basis of diagnosis, limitations, physical therapy examination and evaluation, and in consultation with the physician. Exercise acts in concert with pregnancy to increase heart rate, stroke volume, and cardiac output. However, during exercise, blood is diverted from abdominal viscera, including the uterus, to supply exercising muscle. The decrease in splanchnic blood flow can reach 50% and raises theoretic concerns about fetal hypoxemia Women should avoid becoming overtired. Hypoglycemia occurs more readily during pregnancy necessitating adequate carbohydrate intake Exercise activity should be performed at a moderate rate during a low-risk pregnancy. Aerobic exercise causes a redistribution of blood flow away from the internal organs and toward the working muscles. The maternal respiration rate appears to adapt to mild exercise but does not increase proportionately with moderate and severe exercise when compared with a nonpregnant state. Guidelines for a low-risk pregnancy permit women to remain at 50–60% (12–14 on the Borg scale of perceived exertion) of their maximal heart rate (monitored intermittently) for approximately 15–30 minutes per session
Exercise type	Recommended activities include stationary cycling, swimming, or water aerobics Weight-bearing exercises and high impact exercises should be prescribed judiciously as increases in joint laxity may lead to a higher risk of strains or sprains
Exercise position	Patients should not exercise in the supine position for more than 5 minutes after the first trimester to prevent vena cava compression. To prevent inferior vena cava compression when the patient is lying supine, a folded towel can be placed under the right side of the pelvis so that the patient is tipped slightly to the left. If the supine position is contraindicated, exercises can be performed in side lying, the quadruped position or sitting Positions that involve abdominal compression (flat prone lying) should be avoided in mid to late pregnancy Modifications to exercise for the abdominal muscles must be made for a woman with diastasis recti, as the presence of this condition potentially reduces the ability of the abdominal wall muscles to contribute to their role in trunk and pelvic girdle alignment, motion, and stability Traditional abdominal exercises, such as full sit-ups or bilateral straight leg raises, are not recommended as they may encourage further separation. However, these exercises can be resumed when the separation is less than 2 cm
Exercise environment	Adequate hydration and appropriate ventilation are important in preventing the possible teratogenic effects of overheating. Theoretically, when exercise and pregnancy are combined, a rise in maternal core temperature could decrease fetal heat dissipation to the mother. Some data suggest a teratogenic potential when maternal temperatures rise above 39.2°C (102.6°F), especially in the first trimester

relaxation (either an elevated resting or involuntary relaxation of the pelvic floor muscles) associated with continence and evacuation.[222]

The various types of urinary incontinence are described in Table 30-5. Stress incontinence has prevalence rates that range from 10% to 55% in 15- to 64-year-old females.[229] Although often associated with aging, incontinence due to PFM weakness is not an automatic response to aging and many patients have achieved significant improvement through behavior modification, muscle reeducation, and PFM strengthening.[230,231] Behavior modification techniques include timed voiding schedules, proper toileting techniques, dietary modification, and patient education. Muscle reeducation is primarily used for those patients who do not demonstrate improvement with the PFM strengthening program after approximately 4 weeks. Muscle reeducation can be achieved in a number of ways:

- Biofeedback. A study by Cardozo et al.[232] reported improvements in 81% of patients with urge incontinence who were treated with biofeedback.
- Acupuncture. A study by Philp et al.[233] reported improvements in 77% of patients with urge incontinence who were treated with acupuncture.
- Electrical stimulation. Various forms of electrical stimulation have been used in the treatment of female

TABLE 30-5 Types of Urinary Incontinence	
Type of Urinary Incontinence	**Description**
Functional	Includes people who have normal urine control but are unwilling (impaired cognition) or who have difficulty reaching a toilet in time because of muscle or joint dysfunction or environmental barriers
Stress	Describes the loss of urine during activities that increase intraabdominal pressure such as coughing, lifting, or laughing. Stress incontinence is also particularly noted in high-impact sports that involve running and jumping, gymnastics, and basketball
Overflow	The constant leaking of urine from a bladder that is full but unable to empty due to - anatomic obstruction, for example, prostate enlargement - neurogenic bladder, for example, spinal cord injury
Urge	The sudden unexpected urge to urinate and the uncontrolled loss of urine; often related to reduced bladder capacity, detrusor instability, or hypersensitive bladder

urinary incontinence. Electrical stimulation is an option for patients who demonstrate difficulty with identifying the PFMs or with producing a contraction of these muscles. Transvaginal stimulation with a removable electrode has been in clinical use in Europe and North America for three decades. The typical neuromuscular stimulation system is a portable electrical pulse generator powered by a 9-V alkaline battery. A fully insertable vaginal electrode, which is composed of silicone rubber, is commonly used. Two randomized studies have reported the usefulness of transvaginal electrical stimulation.[234,235] In the study by Sand et al.,[234] comparisons of changes from baseline between active-device and control patients showed that active-device patients had significantly greater improvement in weekly ($p = 0.009$) and daily ($p = 0.04$) leakage episodes, pad testing ($p = 0.005$), and vaginal muscle strength ($p = 0.02$) when compared with control subjects. Significantly greater improvement was also found for both visual analog scores of urinary incontinence ($p = 0.007$) and stress incontinence ($p = 0.02$), as well as for subjective reporting of frequency of urine loss ($p = 0.002$), and urine loss with sneezing, coughing, or laughing ($p = 0.02$), when compared with controls. In the Smith et al.[235] study, of the patients using electrical stimulation in the stress urinary incontinence group, 66% improved, and 72% of the patients with detrusor instability treated with electrical stimulation improved. These rates were not considered statistically significant when compared to traditional therapy, but the authors concluded that electrical stimulation was as safe and at least as effective as properly performed Kegel and drug therapy in the treatment of stress urinary incontinence and detrusor instability. A typical protocol is outlined below[236]

- For patients with urge incontinence: 12.5 Hz for 15 minutes twice a day.
- For patients with stress incontinence: 50 Hz for 15 minutes twice a day.
- For patients with mixed incontinence: 12.5 Hz for 15 minutes a day and 50 Hz for 15 minutes a day.

- In 1948, Kegel first advocated PFM exercise to enhance urethral resistance and promote urinary control.[237] The application of Kegel exercises has been broadened to various applications, but the concentration continues to be considered a useful adjunct in the management of functional urinary incontinence.[228] Many studies have shown that the success of PFM exercise for female stress urinary incontinence depends on the degree and duration of treatment and close supervision by a physical therapist.[238] The patients are initially educated in PFM awareness. Several teaching methods can be used, including verbal cues, visualization with an anatomical model, palpation, objective PFM contraction at the anus, or biofeedback with electromyography recordings via a rectal probe.[239] The method chosen depends on the patient's baseline awareness, coordination, and comfort level. The palpation method is performed as follows:
  - The patient is asked to sit forward on a chair with their legs apart, their spine extended, and their feet flat on the floor. The clinician and patient each place a hand anterior to the ASIS and along the inguinal region to feel the contraction of the transverse abdominis and the internal obliques. The fingers are also spread superiorly to feel the weight of the belly and the RA. The patient is asked to "move the urethra and vagina gently upward" and to maintain the contraction for endurance.

Bracing

The patient is asked to sit forward on a chair with their legs apart, their spine extended, and their feet flat on the floor. The patient is asked to "push their abdomen out" without using an inspiratory effort and to contract the upper and lower RA isometrically in its outer range. The patient is taught to initiate, and hold, this action during a defecatory urge.

Abdominal Drawing-In

The patient is positioned in supine with the spine in neutral and the abdominal wall relaxed. The patient is asked to draw the lower part of the abdomen up and in toward the spine without moving the trunk or pelvis, or using an inspiratory effort, thereby contracting the transverse abdominis and the internal obliques. This exercise is taught in a variety of patient positions, with the appropriate muscles being palpated by the patient and clinician and the use of normal breathing.

Other exercises are added as tolerated. For the following four exercises the patient is positioned in the supine, hook-lying position[238]:

- Exercise 1. The patient performs a PFM contraction with a posterior pelvic tilt.
- Exercise 2. The patient performs a PFM contraction with a bridging motion.
- Exercise 3. The patient performs a PFM contraction with hip adduction against a pillow between the knees.
- Exercise 4. The patient performs a PFM contraction with hip external rotation against an elastic exercise band.

Swiss ball exercises may then be added.[238,240] The patient is positioned sitting on a Swiss ball:

- Exercise 1. The patient performs a PFM contraction with a posterior pelvic tilt in the sagittal plane while rolling on the ball.
- Exercise 2. The patient performs a PFM contraction with a posterior pelvic tilt in the oblique plane while rolling on the ball.
- Exercise 3. The patient bounces vertically on the ball, while performing a PFM contraction during each ascending movement.
- Exercise 4. The patient performs a PFM contraction while rolling on the ball from sitting to standing for functional training with transfers.

Medical management of urinary incontinence is aimed at prevention and may include the following:

- Nutritional counseling to help prevent constipation and to encourage adequate hydration.
- Medications to relieve urge incontinence: estrogen replacement therapy, anticholinergics, alpha-adrenergic blockers to increase bladder outlet/sphincteric tone,

antispasmodics, and combination therapy with tricyclic antidepressant agents and antidiuretic hormone.[241–245]

- Surgical intervention can include catheterization, and surgically implanted artificial sphincters and bladder generators (sends impulses to the nerves to control the bladder function).

The Female Athlete Triad

The female athlete triad, which is relatively common among young women participating in sports, is an interrelationship of menstrual dysfunction, low-energy availability, and decreased BMD.[246] While the number of female athletes suffering from all three aspects of the triad simultaneously is relatively low, there are still many young women who are affected by some component of the spectrum. Each component will be discussed separately.

Menstrual Dysfunction

Normal menstrual cycles are defined by three phases, all of which are governed by alterations in blood levels of estrogen and progesterone:

- Follicular. Increases in ovarian-produced estrogen resulting in endometrial growth, characterized by a compact, proliferative stroma, and increases in endometrial glands in number and length.
- Ovulatory. Ovulation produces the corpus luteum that leads to the production of estrogen and progesterone with progesterone-stimulated production of a secretory endometrium.
- Luteal. The endometrium acquires an edematous stroma with glands that are tortuous and dilated. In the absence of pregnancy, the corpus luteum becomes atretic with a resultant sudden drop in hormonal levels of estrogen and progesterone and then menstruation.

Menarche, or the onset of menstrual periods, normally develops between ages 9 and 16 years in the United States with 12.4 years as the mean age for menarche.[247] The development of menarche is under many influences, including nutritional status, intensity exercise patterns, weight, race, genetic factors, and others.

Abnormal menstrual cycles include the following:

- Amenorrhea: absence of menses for 3 months or more. This is is the most commonly discussed menstrual abnormality and can be further subcategorized into primary and secondary types.
- Primary. This is refers to a delay in the age of menarche (no menses by age 15 years in the presence of normal secondary sexual development, or within 5 years after breast development if that occurs before the age of 10 years).[246,248]
- Secondary. This is refers to a loss of menses after menarche.
- Oligomenorrhea: infrequent, irregular bleeding at > 45 day intervals.
- Menorrhagia/hypermenorrhea: prolonged or excessive uterine bleeding occurring at regular intervals.
- Metrorrhagia: uterine bleeding occurring at irregular but frequent intervals, the amount being variable.
- Menometrorrhagia: prolonged uterine bleeding is occurring at irregular intervals.

In addition to disease and genetic abnormalities, amenorrhea can be caused by energy deficiency and even stress.[249] The effect of exercise on the severity of menarche is inconclusive. However, the side effects of menarche including menstrual pain, edema, bloating, and other symptoms may have a negative impact. The type of amenorrhea resulting from changes in energy availability, which is commonly associated with exercising, is functional hypothalamic amenorrhea (FHA).[246] FHA is characterized by the absence of menses due to the suppression of the hypothalamic–pituitary–ovarian axis, without an identifiable anatomical organic cause.[250] A characteristic of FHA is a decrease in leptin levels. Leptin is a cytokine expressed by adipose tissue and strongly associated with fat mass.[246]

Low-Energy Availability

Energy availability can be defined as the amount of dietary energy for all physiologic functions after accounting for energy expenditure from exercise.[251] Although low-energy availability may be the result of an eating disorder, it can also occur because the athlete feels pressure to maintain a low body weight, or has an inadequate knowledge of nutrition and weight loss.[246] In those cases where an eating disorder, such as anorexia nervosa or bulimia nervosa is suspected, the clinician should be aware of the physical signs of persistent vomiting (Russell sign, calloused knuckles), gingival abrasions, parotid enlargement, and loss of dental enamel.[250]

Decreased Bone Mineral Density

In general, young healthy women achieve 92% of their total body bone mineral content by 18 years of age and approximate 99% by age 26 years.[252] Although healthy female athletes tend to have a higher bone and mineral content than their nonathletic counterparts, amenorrheic athletes have a lower bone mineral content than their eumenorrheic counterparts to such a degree that their menstrual status may override the beneficial effects of physical activity on bone.[246]

Given the complexity of the female triad, a multidisciplinary approach is usually necessary for recovery. The primary goal of treatment is restoration of regular menstrual cycling and enhancement of BMD.[246]

Breast-Cancer–Related Lymphedema

The lymphatic system comprises strategically placed lymph nodes connected by a network of lymphatic vessels, which act as the circulatory system for the immune system.

CLINICAL PEARL

The lymphatic system has four major purposes:

- To return proteins, lipids, and water from the interstitium to the intravascular space.
- To act as a safety valve for fluid overload and to help keep edema from forming.

- To maintain the homeostasis of the extracellular environment.
- To cleanse the interstitial fluid and provide a blockade to the spread of infection or malignant cells in the lymph nodes.

Larger lymph collectors, known as trunks or ducts, handle these larger volumes of lymph fluid. The majority of the lymph produced by the body in a 24-hour period (2–4 L) returns to the heart. As lymph fluid moves more centrally, the diameter of lymph vessels increases. The major lymph nodes are the submaxillary, cervical, maxillary, mesenteric, iliac, inguinal, popliteal, and cubital nodes. Lymphedema results from a mechanical insufficiency that arises in an area, when lymph collectors sustain functional and structural damage. Breast-cancer–related dysfunction of the lymphatic system and subsequent lymphedema of the UE can occur as a complication of the treatment for breast cancer. Current treatment for breast cancer usually involves removing a portion or all of the breast accompanied by excision or radiation of the adjacent axillary lymph nodes, the principal site of regional metastasis.[253] In addition to UE lymphedema, other complications include loss of shoulder mobility and limited function of the arm and hand.[254]

The other impairments and complications that may occur in association with the treatment of breast cancer are listed in Table 30-6.[253] The most common method to diagnose and measure UE lymphedema is circumferential measurements using specific anatomical landmarks to estimate volume differences between the affected and unaffected extremities. A more accurate measure of volume difference is the water displacement technique using a volumeter.

The intervention for breast-cancer–related lymphatic dysfunction includes the following[253]:

- Strengthening exercises. Exercise encourages muscle contractions to provide the primary pumping mechanism for lymphatic and venous drainage. Progressive resistance training (using light weights initially and progressing as tolerated) for the major muscle groups of the upper trunk and UE are emphasized (e.g., seated row, bench press, latissimus dorsi muscle pull-down, triceps muscle extension, and biceps curl.[255]
- Aerobic exercises. After 2 weeks, an arm ergometer can be introduced as an upper-body aerobic exercise. Moderate-intensity aerobic conditioning exercises are added as tolerated.

TABLE 30-6 Impairments and Complications Associated with the Treatment of Breast Cancer

Incisional pain
Posterior cervical and shoulder girdle pain
Vascular and pulmonary complications including pneumonia and deep venous thrombosis (DVT)
Chest wall adhesions
Weakness of the involved UE
Postural malalignment
Fatigue and decreased endurance

Data from Kisner C, Colby LA. Management of vascular disorders of the extremities. In: Kisner C, Colby LA, eds. Therapeutic Exercise. Foundations and Techniques. 5th ed. Philadelphia, PA: FA Davis;2002:825–849.

CLINICAL PEARL

Traditional pneumatic compression devices are generally contraindicated for lymphedema because the natural drainage system has been damaged, and these devices can potentially cause more damage to the system. Instead, various types of specialized wrapping, taping, and lymphedema massage are advocated, followed by pressure garment wear.

- ROM exercises. Individualized shoulder (Chapter 16) and cervical (Chapter 25) ROM exercises to address any muscle imbalances.
- Massage and wrapping. Various types of specialized wrapping, taping, and lymphedema massage are advocated, followed by pressure garment wear.

Although traditionally popular, pneumatic compression devices are not currently prescribed for lymphedema because the natural drainage system has been damaged, and these devices can potentially cause more stress to an already-damaged system.

Low Bone Mineral Density

Low BMD includes osteopenia or osteoporosis (see Chapter 5). A low BMD has been associated with a significant risk for falling in postmenopausal women.[256,257] However, structured exercise therapy programs including progressive, high-intensity resistance exercises, in postmenopausal women with low BMD have been shown to improve QoL.[258]

The Swimming Athlete

Swimming is a unique sport that combines upper and lower extremity strength exercises with cardiovascular training in a nonweight-bearing environment.[259] Swimmers at the elite level may swim up to 9 miles per day, with an average of 4,000 shoulder revolutions. The highly repetitive motion that occurs in the various swimming strokes, including freestyle, butterfly, backstroke, and breaststroke, can predispose elite swimmers to a variety of musculoskeletal injuries. The freestyle stroke is the most common stroke studied and is divided into two major phases called the pull-through, and recovery. The pull-through phase is the time during which the arm is in the water generating a propulsive force, whereas the recovery phase is the time the arm is out of the water repositioning for another pull through. The pull-through phase is further subdivided into four sub phases called hand entry (Fig. 30-9), catch (Fig. 30-10), mid pull-through (Fig. 30-11), and late recovery (Fig. 30-12). The recovery phase has three sub phases called elbow lift (Fig. 30-13), mid recovery (Fig. 30-14), and late recovery (Fig. 30-15) (Table 30-7). One other important component to a swimmer's efficiency is the streamline position, which the swimmer adopts at the start and immediately after each turn in an attempt to minimize the resistance of

FIGURE 30-9 Hand entry.

FIGURE 30-16 The streamline position.

the water and to allow the swimmer to maintain speed while resting. T e streamline position involves the swimmer placing both hands, one on top of the other, directly above the head with the elbows extended, thus requiring 180 degrees of abduction with near end range external rotation (Fig. 30-16), which can stress the shoulder anteriorly and potentially provoke subacromial impingement.

T e most common areas of the body for injury in elite swimmers are the shoulder, knee, and spine.

Shoulder Injuries

Shoulder injuries, referred to collectively as "Swimmer's shoulder," are the most common injuries in elite swimmers with a prevalence between 40% and 91%.[260] T e most common shoulder injuries that occur with elite swimmers are as follows[259]:

- Shoulder impingement. A 2010 study,[261] which looked at 80 young elite swimmers (13–25 years old), reported a positive impingement sign in 84% (67) of the swimmers, while 69% of the 52 summers examined demonstrated

TABLE 30-7 The Subphases of the Freestyle Stroke

Subphase	Description of Shoulder and Body Biomechanics
Hand entry	The shoulder is positioned in external rotation and abduction with the ipsilateral side of the body rolling down deep into the water
Catch	The shoulder is brought into internal rotation near full elevation. This is a critical step in the pull through phase and enables the swimmer to have the largest palm and forearm surface area to pull through the water. It is also a common point where stroke mechanics break down secondary to fatigue or pain
Mid pull through	The shoulder is in neutral rotation and 90 degrees of elevation. At this point the body roll into the water is at its maximal point, being 40–60 degrees from horizontal
Late pull through	The shoulder is in internal rotation and adduction as the arm moves to the swimmer's side. The posterior structures of the shoulder are potentially stressed by this abducted and internally rotated position. The body rolls to return to near horizontal
Elbow lift	The shoulder is positioned in internal rotation and adduction as the ipsilateral side of the body rolls up and out of the water
Mid recovery	The shoulder is at 90 degrees of abduction and slight external rotation. Failure to initiate shoulder external rotation through fatigue of the external rotators can prevent the shoulder from achieving this position, leading to increased time spent in an impingement position. At this point, the body roll is also at its maximum position out of the water being 40–60 degrees from horizontal
Late recovery	The shoulder returns to external rotation and abduction to prepare for hand entry. The anterior structures of the shoulder are potentially stressed by this abducted and externally rotated position. The ipsilateral side of the body begins to roll deep into the water as the arm attempts to enter the water with as little resistance as possible

Data from Herzog A, Martin R, Scibek JS. Shoulder injuries in swimmers: causes, evaluation, and treatment. Orthop Phys Ther Pract. 2013;25(3):146–151.

signs of supraspinatus tendinopathy with an MRI.
Shoulder impingement can occur in swimming at various times in the stroke:

a. During the recovery phase in swimming strokes such as the butterfly and freestyle, the glenohumeral joint is in a position of forward flexion and internal rotation, which is a characteristic position for subacromial impingement.
b. At the point when the hand enters the water. All of the four strokes in competitive swimming—butterfly, backstroke, breaststroke, and freestyle—require excessive internal rotation with elevation to initiate a forceful pull as the hand enters the water. T e high dynamic forces applied on the hand generate a large moment in the shoulder joint, causing elevation of the humeral head and subsequent impingement.[259]
c. During the late pull-through phase of the stroke, hyperextension of the UE pushes the humeral head anteriorly and rotates it internally, which could possibly aggravate an impingement, especially if muscle fatigue is present.[262]
d. An incorrect hand entry that crosses the midline of the long axis of the body can cause impingement of the supraspinatus and the long head of the biceps.

- Muscle overuse and fatigue. As described in Chapter 16, a number of shoulder muscles are involved to propel the body through the water, the most important of which are as follows[259]:

a. Teres minor. T is muscle provides an external rotation force and stabilizes the humeral head in conjunction with the pectoralis major.
b. T e serratus anterior. T is muscle helps to position and stabilize the scapula.
c. Subscapularis. T is muscle acts as an internal rotator throughout the stroke.
d. T e pectoralis major and latissimus dorsi. T ese muscles generate the majority of the adduction and internal rotation force of the UE.

T e repeated contraction of these muscles during swing makes them prone to fatigue.[263]

a. Glenohumeral joint laxity. Working together, the static and dynamic stabilizers of the shoulder control excessive translation of the humeral head (see Chapter 16). Several studies have shown an association between increased shoulder laxity and shoulder pain in swimmers.[264,265] Although in most swimmers, the laxity is multidirectional, backstroke swimmers generally experience isolated anterior glenohumeral instability due to the position of the arm in overhead elevation and external rotation at hand entry.[259] T e increase in laxity found in swimmers is thought to overload the dynamic stabilizers, and result in muscle fatigue.

Knee Injuries

A greater incidence of knee pain occurs in breaststroke swimmers than in other swimming techniques.[259,266,267] T e biomechanics of the breaststroke generates high valgus loads at the knee due to the adducted hip position. T ese loads result in increased tension across the medial compartment and increased compression of the lateral compartment.[268,269] In addition, extreme hip abduction angles at kick initiation can be detrimental.[259] T e pain is predominately felt in the medial compartment of the knee, although anterior knee pain is also common.[259] T e other strokes in swimming can also produce knee pain. For example, the flutter kick in freestyle swimming can result in patellofemoral overload due to the required repetitive contraction of the quadriceps.[270] In addition, the classic wall push-off used by swimmers can increase patellofemoral contact stresses when the knee is in a high degree of flexion, or during starts and turns when the knee is in a partial squat position.[270]

Spine Injuries

Although low back injuries are more common in elite butterfly swimmers and elite breaststroke swimmers due to the amount of hyperextension of the lumbar spine required, they can occur with the other strokes in elite swimming.[271] T e main variables appear to be training intensity, duration, and distance. An additional risk factor is the use of training devices such as fins, kick boards, or pull buoys as these can produce excessive hyperextension of the lumbar spine.[272]

As the incidence of pain and injury in swimmers is often the result of poor stroke technique, it is essential that the athlete and trainer be able to recognize stroke alterations. For example, a dropped elbow in the recovery phase of the freestyle stroke, which decreases the degree of humeral internal rotation, is a sign of subacromial impingement.[259] Other biomechanical errors to look for during freestyle include a dropped elbow during the pull-through phase (Fig. 30-17), an eyes-forward head-carrying angle, late shoulder external rotation (Fig. 30-18), incorrect hand position during hand entry, incorrect hand entry angle, an incorrect pull-through pattern, and inadequate body roll (Table 30-8).[273] In addition to instruction on the various stroke-specific mechanics, every swimmer must be put through an extensive program of stretching, strengthening, and endurance training that is

FIGURE 30-17 Dropped elbow.

FIGURE 30-18 Late shoulder external rotation.

as specific to their stroke as possible. Emphasis should be placed on abdominal and scapular muscle strengthening (Figs. 30-19 and 30-20A–,B), quadriceps/hamstring stretching and strengthening, and exercises to improve both the strength and flexibility of the hip internal and external rotators.[259] T e shoulder and core musculature can be challenged by having the patient lie prone on a Swiss ball and rotating the trunk from side to side (Fig. 30-21A–B). Finally, as the volume of training is a significant contributor to injury in swimmers, care must be taken to not overtrain these athletes and to provide sufficient recovery time. In a swimming competition, athletes often exert maximum performance with little time to rest between competitions, increasing the possibility of lactate accumulation, or lactatemia.[274] Some of these negative effects can be offset by using regeneration (light training) exercises both in and out of the pool, massages, and immersion in cold water.[274]

TABLE 30-8 Freestyle Biomechanical Parameters

Phase of Stroke	Correct Biomechanics	Incorrect Biomechanics	Clinical Signif cance of Incorrect Biomechanics
Hand entry	The hand should enter the water anterior and lateral to the head, and medial to the shoulder The fingers should enter the water first[a]	The hand enters further away from, or crosses, the midline of the long axis of the body[a,b] The thumb enters the water first[a]	Increases anterior impingement, as it mimics the Neer impingement testing position (see Chapter 16) Stresses the biceps attachment to the anterior labrum[a]
Pull-through	The elbow is kept higher than the hand and pointed laterally throughout the pull The pull-through should be straight back The arm crosses the midline of the swimmers body (adducting)	The elbow drops during the pull through, causing the shoulder to not be internally rotated to the extent necessary to maintain the elbow closer to the surface of the water than the hand An S-shaped pull through is used, or there is excessive horizontal adduction past body midline during pulling[a]	Increases the amount of external rotation, which places the propulsion muscles at a mechanical disadvantage resulting in an inef cient pull Increases time spent in the impingement position. Mimics the Hawkins-Kennedy impingement testing position (see Chapter 16)
Recovery	The elbow is kept higher than the wrist throughout the recovery phase[a] There is a body roll of approximately 45 degrees along the longitudinal axis of the body[a]	The elbow drops during the recovery phase and the elbow enters the water before the hand The body roll is greater or less than 45 degrees [a]	The upward force of the water on the dropped humerus, secondly to external rotator weakness or fatigue, leads to its superior translation and subacromial impingement Excessive rolling can lead to an incorrect crossover hand entry, or pull through position. An insuf cient roll during recovery can increase mechanical stress on the shoulder and lead to improper hand entry position[a]
All phases	The head is maintained in the neutral position[a]	The head is maintained in an eyes forward position[a]	The eyes forward head position increased impingement by impeding normal scapulothoracic motion[a]

FIGURE 30-19 Abdominal and scapular muscle strengthening exercise.

CLINICAL PEARL

Swim volume-induced supraspinatus tendinopathy with associated supraspinatus tendon thickening may be an intrinsic risk factor for the development of swimmer's shoulder.[275]

The Rowing Athlete

The origins of rowing began sometime after 1000 BC when it was discovered that an oar working against a fulcrum was mechanically more efficient than a paddle and that a sliding seat allowed greater force to be exerted against the oar, thus generating more boat speed.[276] Rowing has since grown to be a very popular water-based sport and land-based fitness and recreational activity. The popularity from the fitness community is based on the fact that rowing provides a full body workout, enhancing strength, while also improving cardiovascular endurance and fitness (see Chapter 15). However, as rowing requires a continuous repetitive motion, it is prone to a number of overuse injuries including the following[276]:

Rib and Thorax Injuries

The majority of rib and thorax injuries associated with the rowing are rib stress fractures, most commonly affecting the fifth through ninth rib.[277,278] Biomechanical analysis of the ribs predicts that the bending moment occurs at the middle third of the rib in its posterolateral segment, and that the opposing actions of the serratus anterior and external oblique muscles are major contributors to the development of a stress fracture.[277] The serratus anterior fires maximally at the catch phase of the rowing stroke (the point at which the rower begins to pull the oar through the water), while the external oblique muscle increases the lateral segment bend of the rib by pulling it inward and downward.[276] The opposing action of these two muscles results in repetitive bending forces in the middle segment of the rib which, if intense enough, can produce a stress fracture.[276] The common findings for a rib fracture are described in Chapter 5. The intervention strategies for a rib fracture are described in Chapter 27.

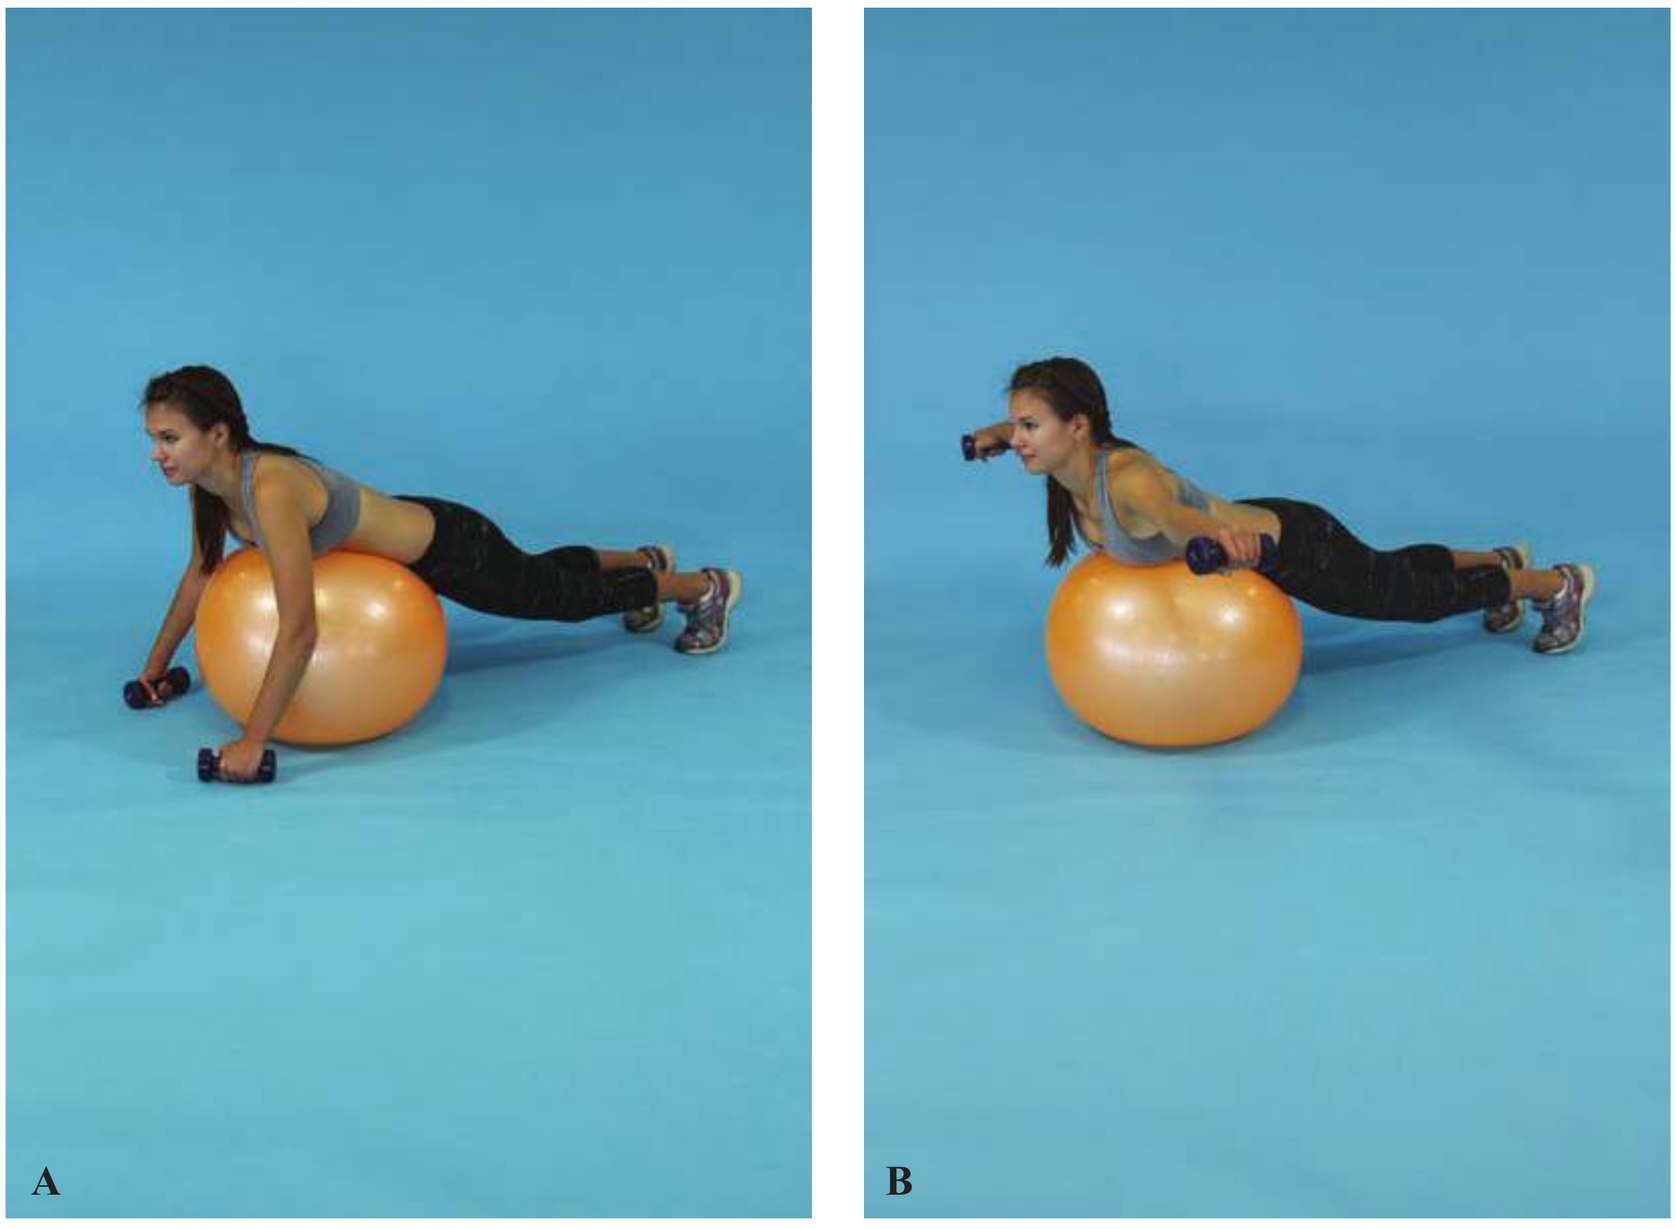

FIGURE 30-20 Abdominal and scapular muscle strengthening exercise. A. Start. B. Finish.

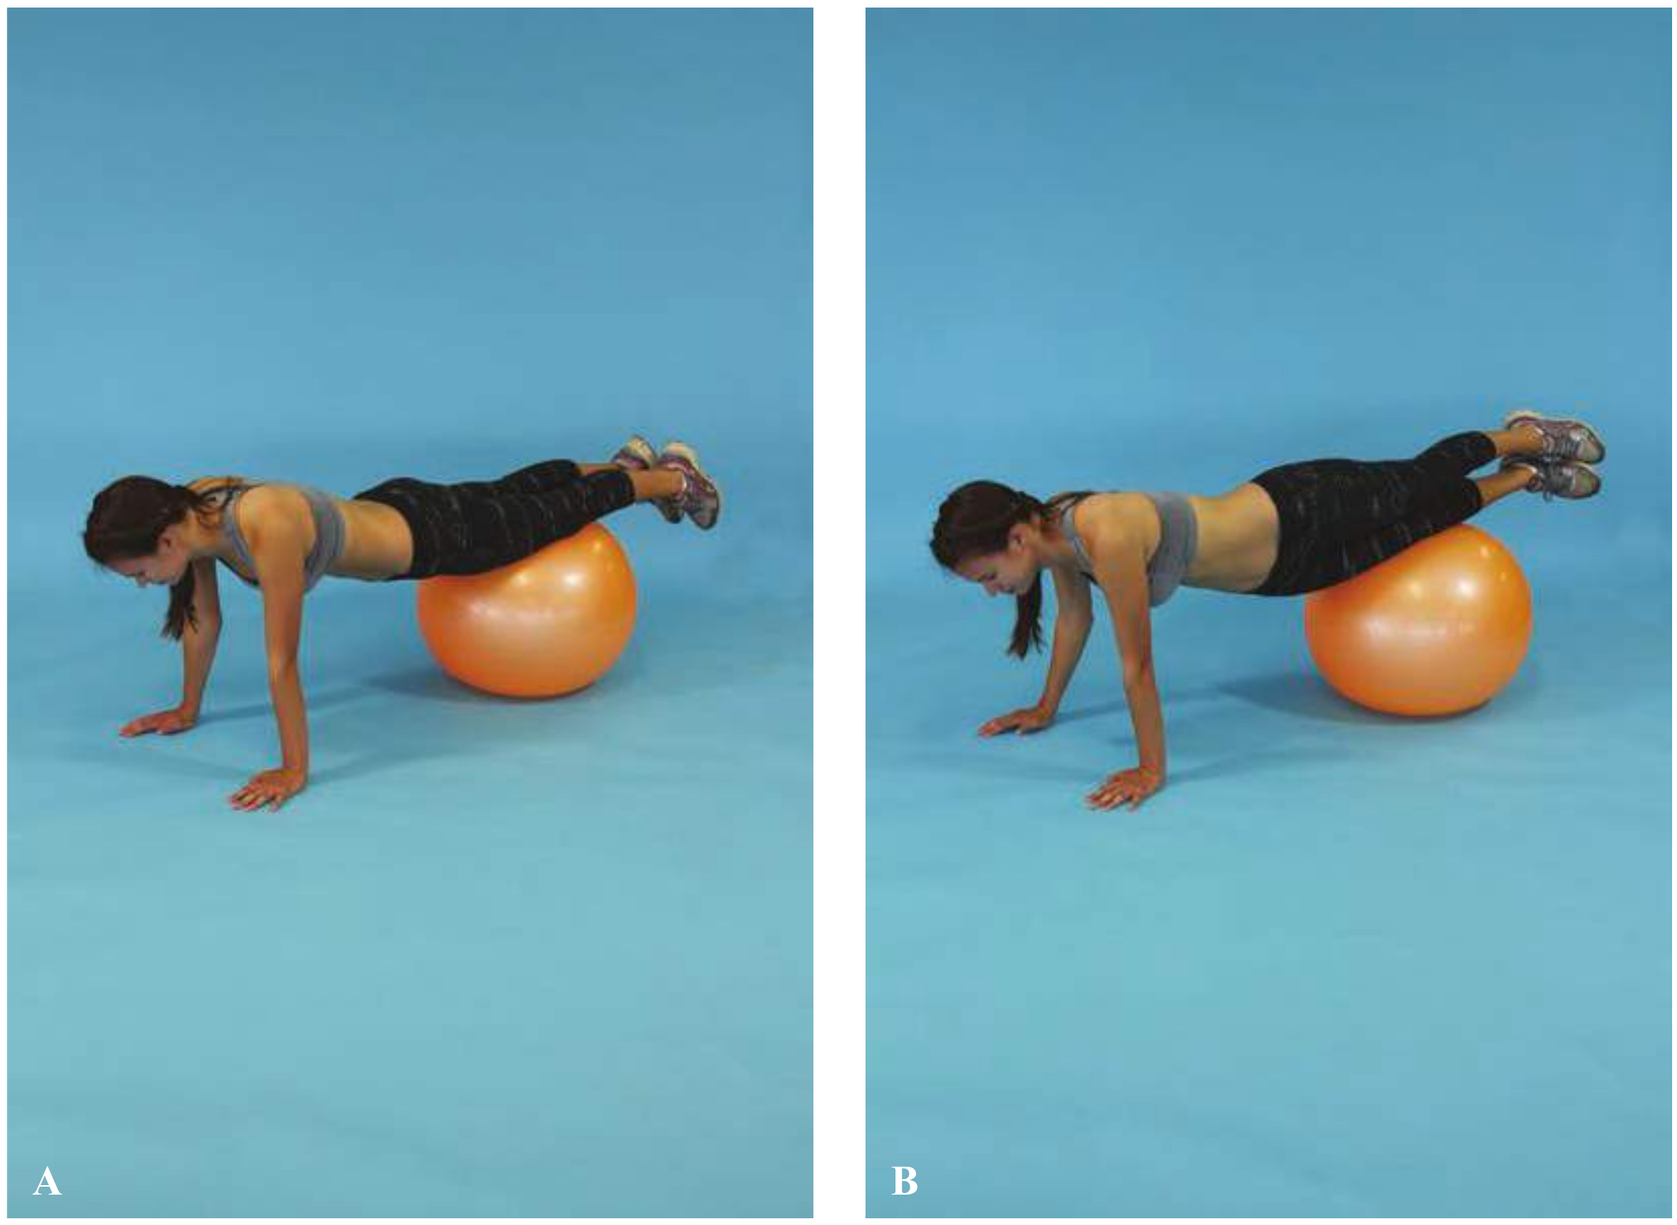

FIGURE 30-21 Rotation of the trunk from side to side.

Low Back Pain

Given the extreme positions placed on the low back during the various phases of the rowing stroke, it is not surprising that LBP is a common complaint in the rowing population. The back functions as a brace cantilever during the rowing stroke and is the major connection in the transfer of power from the legs to the oar.[276] At the catch, there is a rapid generation of force at the oar which accelerates to a peak at the mid-drive and tapers to the finish. This force results in an anterior shear loading of the lumbar spine with the peak forces occurring as the spine passes over the pelvis into the extended position at the end of the stroke.[276] A number of factors have been associated with the development of back pain in the intercollegiate rowing population and include[279]:

- Rowing before age 16 years.
- The hatchet oar.
- Training with free weights.
- Training on an ergometer rowing machine for longer than 30 minutes.
- Pre-existing history of LBP.

The examination, diagnosis, and treatment of LBP are described in Chapter 28.

Patellofemoral Joint Pain

Rowing involves extreme loading of the patellofemoral joint (PFJ). In addition, training activities designed to increase the strength of the quadriceps mechanism, including stair running and squat jumps, cause significant pressure at the PFJ.[276] The clinical findings and intervention strategies for PFJ pain are described in Chapter 20. In addition, the following modifications can be made[276]:

- Increasing the height of the foot stretcher can reduce PFJ compression.
- Changing the rotation of the toe-in or toe-out position of the sneakers can alter the functional knee varus or valgus.
- The arc for knee flexion or extension can be limited by the use of frontal backstops placed on the track of the sliding seat of the shell or the ergometer.

Iliotibial Band Friction Syndrome

Iliotibial band friction syndrome (ITBFS) is fairly common in the rowing population due to the repetitive flexion of the hips and knees involved. The clinical findings and intervention strategies for ITBFS are described in Chapters 19 and 20.

Wrist Extensor Tenosynovitis

During the rowing stroke on water, the oar blade is removed from the water at the finish. The oar is then rotated (feathered) parallel to the water before being re-rotated perpendicular to the water prior to entering the water. The abductor pollicis longus (APL), the extensor carpi radialis longus (ECRL), and the extensor carpi radialis brevis (ECRB) are firing during feathering. Hypertrophy of the APL and ECRB can result in tenosynovitis of the radial wrist extensors.[276] The typical presentation is pain, swelling, and crepitus with motion of the involved tendons. Conservative intervention involves rest with the use of a cock-up wrist splint, anti-inflammatory medication, and physical therapy modalities, such as ultrasound and whirlpool.[276]

The Throwing Athlete

T e act of throwing involves the entire kinetic chain but especially places the UE through extreme stresses, particularly at the elbow and shoulder. To throw efficiently, an individual must transfer energy from the ground to the legs, hips, trunk, upper arm, forearm, and finally to the ball.[280,281] Unless this transfer of energy follows the correct sequence, excessive stress can be focused on a single body segment. Baseball pitching is a specific form of throwing that requires extensive training to be performed correctly. If performed incorrectly, significant stresses can be placed on the individual body segments involved throughout the various phases of the technique. Baseball pitching has been described in six stages[282,283]:

- Wind-up. T is phase, which describes the movement from the start position until the hands separate, involves the initial preparation as the pitcher initiates the throw. Typically, both feet begin with even weight distribution before the thrower then pivots to a position parallel to the rubber. As this is occurring, the elbow is flexed, and the forearm is slightly pronated, and the lead leg is lifted by a concentric contraction of the hip flexors. T e stance leg, which bends slightly, is controlled by eccentric contraction from the quadriceps muscle until a balanced position is achieved at which point the quadriceps and hip abductors contract isometrically. In the UE, the shoulders are partially flexed and abducted and, as the hands come together, the elbow flexion is maintained by an isometric contraction of the elbow flexors. During this phase, UE muscle activity is low.
- Stride. During this phase, the hands and arms separate and both arms swing down and then up, while the lead leg begins to fall down and forward, until the lead foot contacts the ground. T e lead leg is controlled by the eccentric action of the hip flexors as the lead hip begins to externally rotate, and the stance hip begins to internally rotate. T e front foot, which is pointed slightly inward, should be planted slightly to the third-base side (for a right-handed pitcher)—a closed stance occurs if the lead foot lands to the right of the stance foot, whereas an open stance results if the lead foot lands to the left of the stance foot. Improper lead foot placement can result in the thrower "throwing across the body." If the lead foot is positioned excessively closed (which minimizes the contribution of the lower body), early pelvis rotation occurs (which causes energy from the pelvis rotation to be applied to the upper trunk prematurely). In the upper extremities, as the lead foot makes contact, the shoulder is abducted approximately 90 degrees and approximately 60 degrees of external rotation, while the throwing arm is positioned slightly behind the trunk and approximately in 10–35 degrees of horizontal abduction. T e triceps muscle of the throwing arm contracts to isometrically and eccentrically control the elbow angle, while the wrist and finger extensors concentrically move the wrist from slight flexion to hyperextension.[284,285]
- Arm cocking. T is phase, which describes the period from foot contact until maximum shoulder external rotation as the upper body is rotated to face the target, begins when the ball leaves the nondominant gloved hand and ends when the forward foot comes into contact with the ground. T e pelvis rotates, and then the upper trunk rotates. T e quadriceps of the lead leg initially exhibits an eccentric action to decelerate knee flexion after foot contact, and then an isometric action, together with high activity from the gluteus maximus, to stabilize the lead leg. In the upper extremities, elbow flexion between 90 and 120 degrees and increasing forearm pronation to approximately 90 degrees occurs in the throwing arm. Dynamic stability is provided by the flexor–pronator muscle mass, and the triceps contracts isometrically to limit elbow flexion.[285] During this phase, high shoulder joint forces and torques are generated as the shoulder horizontally abducts at the time of maximum shoulder external rotation.
- Arm acceleration. T is phase, which describes the period from maximum shoulder external rotation until ball release, is characterized by the generation of a significant anteriorly directed force on the UE by the shoulder musculature, resulting in internal rotation and adduction of the humerus, accompanied by rapid elbow extension. T e period from the late phase of arm cocking through the acceleration phase is the time when the elbow is subjected to maximum valgus stresses.[286] During this phase, the trunk tilts anteriorly, the hip flexes, and the lead knee extends.
- Arm deceleration. T is phase describes the period between when the ball is released until maximum shoulder internal rotation. T e trunk and hips continue to flex and the lead knee and throwing elbow continue to extend until almost full extension is reached. T e posterior muscles of the shoulder have an important role in resisting shoulder distraction and anterior subluxation forces during this phase.
- Follow-through. T is phase, which describes the period from maximum shoulder internal rotation until a balanced position is achieved, is characterized by the dissipation of all excess kinetic energy as the trunk flexes forward, the elbow reaches full extension, and the arm crosses in front of the body.

T e two main joints most impacted in the throwing athlete are the shoulder and the elbow.

Shoulder Injuries

Isolated shoulder injuries are not common in this population. More often, the shoulder injuries involve a number of structures including the rotator cuff (internal and external impingement), the labrum-biceps complex (labral tears), the scapula (snapping scapula), and the capsule (anterior shoulder instability, and posterior capsule syndrome).[283] In addition, spiral fractures of humeral shaft can occur, as can suprascapular nerve entrapment (see Chapter 3).[283]

T e rehabilitation following a shoulder injury is dependent on the structure involved but typically follows the progressions described in Chapter 16.

Elbow Injuries

Approximately 22–26% of all injuries to major-league baseball pitchers involve the elbow joint.[287] T is is largely due to

TABLE 30-9 Rehabilitation of the Overhead Athlete's Elbow

Phase	Rehabilitation Guidelines	Goals
1. Immediate motion	▯ Pain-free ROM activities performed in all planes of elbow and wrist motions ▯ Active-assisted and passive ROM exercises performed at the humeroulnar joint to restore flexion and/or extension and the humeroradial and radioulnar joints for supination/pronation. LLLD stretching techniques for 10–15 minutes can be used ▯ Grade I–II joint mobilizations ▯ Sub painful and submaximal isometrics for the wrist, forearm, and elbow muscle groups ▯ Scapular muscle strengthening	Minimize the effects of immobilization, reestablish nonpainful ROM, decrease pain and inflammation, and retard muscular atrophy. The primary goal is to restore preinjury elbow extension ROM
2. Intermediate	▯ Continuation of stretching exercises to maintain full elbow and wrist ROM ▯ Grade III and IV joint mobilizations ▯ Exercises to increase flexibility of the wrist flexion, extension, pronation, and supination ▯ Shoulder flexibility exercises with emphasis on external and internal rotation at 90 degrees of abduction, flexion, and horizontal adduction ▯ Progression of strengthening exercises from concentric to eccentric for elbow flexion and extension, wrist flexion and extension, and forearm pronation and supination ▯ Progressive strengthening of the glenohumeral and scapulothoracic muscles ▯ Introduction to Thrower's Ten Program (Table 16-34) ▯ Neuromuscular control exercises	To maintain and enhance elbow and UE mobility, improve muscular endurance and strength, and reestablish neuromuscular control of the elbow complex
3. Advanced strengthening	▯ A gradual progression to higher resistance, functional movements, eccentric contractions, and plyometric activities	To gradually increase strength, power, endurance, and neuromuscular control to prepare for a gradual return to sport
4. Return to activity	The athlete must exhibit full pain-free throwing ROM, no pain or tenderness, a satisfactory isokinetic test, and medical clearance The athlete is progressed through an interval throwing program which begins with a long toss program and progresses to throwing off a mound before increasing the number of throws, intensity, and type of pitch	Allow the athlete to progressively return to full competition

ROM, range of motion; LLLD, low-load, long-duration.

Data from Wilk KE, Macrina LC,. Cain EL, et al. Rehabilitation of the overhead athlete's elbow. Sports Health. 2012;4: 404–414.

the repetitive overhead motion required of these athletes, and the subsequent chronic stress overload or repetitive microtraumatic stress that occurs. T e forces that act at the elbow are maximal during the acceleration phase of throwing. For example, as the elbow extends at over 2,300 degrees per second, creating a medial shear force of 300 N, and a compressive force of 900 N to the lateral aspect of the elbow.[288–290] In addition, during the acceleration phase of throwing, the valgus stress applied to the elbow is 64 Nm, which exceeds the ultimate tensile strength of the ulnar collateral ligament.[291]

T e rehabilitation following an elbow injury or elbow surgery can be broken down into four phases (Table 30-9). Progression from the immediate motion to intermediate phase is initiated when the following are achieved[290]:

- ▯ Full throwing ROM (as compared to prior to the injury)
- ▯ Minimal pain and tenderness.
- ▯ A good (≥ 4/5) manual muscle test of the elbow flexor and extensor musculature.

Progression from the intermediate phase to the advanced strengthening phase is initiated when the following are achieved:

- ▯ Full nonpainful external and internal rotation total ROM
- ▯ No pain or tenderness
- ▯ Strength that is 70% of the contralateral extremity

The Tennis Athlete

T e game of tennis predominantly involves three distinctly different types of strokes: the two groundstrokes (the forehand

and the backhand) and the serve. T ese strokes can be broken down into four phases:

- Preparation phase. T is phase begins from the first sign of movement until the backward arm movement is completed.
- Arm cocking phase. T is phase involves the correct positioning of the racket head prior to striking the ball.
- Acceleration phase. T is phase begins when the racket makes contact with the ball and last until the end of ball contact.
- Follow-through phase. T is phase begins immediately post ball contact and continues through the end of the stroke motion.

T e average elite tennis match involves at least 100 repetitions of "game" serves, and 250 repetitions of "game" groundstrokes.[292] Of the three strokes, it is the serve that is the most complex in competitive tennis. T e complexity of the movement results from the combination of limb and joint movements required to summate and transfer forces from the ground up through the kinetic chain and out into the ball.[293] Although there are similarities between the throwing motion in baseball and the tennis serve, the following differences exist[293]:

- T e planes of motion that are involved.
- T e nondominant arm tossing the tennis ball.
- T e trajectory of forces produced and released.
- T e tennis racket, which alters the lever arm.
- T e technical components of the serve.
- T e variety of placements and goals of the motion (spin, speed, angle, directional, etc.).

T e three phases of the tennis serve can be broken down into a number of sub stages, which are as follows[293]:

- Ball release. T is phase describes the time from when the ball and racket are at rest until the ball is released from the nonserving hand (left hand in this description). T e activity of the right erector spinae increases steadily from the beginning of the serve through the end.[294] T e location of the toss relative to the player affects arm abduction and subacromial humeral position—if the toss is located too close to the head (12 o'clock position) arm abduction is increased and can cause subacromial impingement.[295]
- Lower body loading. T is phase, which is designed to position the body segments to generate potential energy, describes the time when the lower body becomes fully loaded and coincides with the elbows lowest vertical position, and maximum knee flexion. T e greater the muscle force generated during this phase, the greater the velocity.
- Arm cocking. T is phase, which depends on an efficient loading stage, describes the period from the end of the loading stage until maximal shoulder external rotation, which coincides with the tip of the racket head pointing toward the ground. High internal rotator eccentric loads are applied during the late cocking phase. Maximum shoulder external rotation occurs at a fraction of a second before contact in professional tennis players and, coupled with the position of shoulder abduction at this point, can lead to injury with repetition.
- Acceleration. T is phase describes the period from the end of the arm cocking phase until the racket contact with the ball. Elite servers have a quicker acceleration phase than do beginner servers as a result of a more vigorous knee extension.[296]
- Contact. T is very short phase describes the point at which the ball and racket impact. Elite tennis players generate racket velocities of approximately 38–47 m/s (85–105 mph).[297]
- Deceleration. T is phase describes the period after the racket makes contact with the ball as the upper and lower extremities decelerate. T e deceleration phase involves eccentric loads on both the upper and lower body.

Given the forces and torques involved, and the abducted position of the UE at the point when the maximum forces are generated, it is perhaps not surprising that shoulder injuries are common in tennis players. However, in addition to other UE injuries (wrist and elbow), the tennis player is also prone to lower extremity injuries, and trunk injuries.

The Running Athlete

T e highly repetitive motion that occurs with running predisposes many runners with a number of overuse injuries including the following:

Pelvic Stress Injuries

Stress fractures account for 15% of injury suffered by running athletes, 4% of which occur about the pelvis.[298] Pelvic stress injuries can occur at the sacrum, inferior pubic rami, and femoral neck. As with other stress fractures, normal bone begins to fail when exposed to repeated bouts of excessive forces and an inability of the nearby musculature to absorb the shear forces and/or traction forces acting on the bone. T ese overloading forces alter the normal bone homeostatic mechanism allowing osteoclastic function to predominate and provoke the injury cascade.[298] Several risk factors for developing a stress injury have been identified, including both intrinsic and extrinsic risk factors. T e intrinsic risk factors include the following[299]:

- Female gender.
- Amenorrhea.
- Low BMD.
- Load lean body mass.
- Poor aerobic fitness at onset of an exercise regimen.
- Genu valgum.
- Leg-length discrepancy.

T e extrinsic risk factors include the following[299]:

- Rapid progression of a training program.
- Running on an irregular or angulated surface.
- Running and jumping sports.
- Deteriorated footwear.
- Smoking.
- Poor nutrition.

The typical conservative approach for pelvic stress injuries involves removal from the offending activity until symptoms have resolved, while simultaneously maintaining cardiovascular fitness, muscular strength, and neuromuscular control without stressing the injured area. Patient education is important to prevent recurrence. This includes proper progression of a training program, cross training, and regular exposure to different training surfaces.[299]

Osteitis Pubis/Athletic Pubalgia

This condition, which typically occurs in individuals who participate in sports producing twisting/shearing forces such as soccer, rugby, ice hockey, and American football, is described in detail in Chapter 29.

Snapping Hip Syndrome

See Chapter 19.

Iliotibial Band Friction Syndrome

See Chapter 19 and 20.

Shoulder complex
goniometry of, 527–534, 532f–535f
adduction, 533, 533f
extension, 532–533, 533f
external rotation, 533, 534f–435f
flexion, 527–532, 532f
internal rotation, 533, 534f
testing of, 470–476, 470f–476f
deltoid muscles, 47ff, 474–475, 474f
latissimus dorsi muscle, 472–473, 472f
long head of biceps brachii, 476
lower trapezius muscle, 471, 471f
middle trapezius muscle, 471, 471f
pectoralis major muscle, 473, 473f, 474f
pectoralis minor muscle, 473–474, 474f
rhomboid major, minor, and levator scapulae muscles, 472, 472f
rotator cuff muscles, 475–476, 475f–476f
serratus anterior muscle, 471–472, 471f–472f
teres major muscle, 473, 473f
upper trapezius and levator scapulae muscles, 470–471, 470f
Shoulder exercises, 744
Shoulder extensors, gross muscle testing, 468f
Shoulder flexors, gross muscle testing, 468f
Shoulder Pain and Disability Index (SPADI), 621
Shoulder subluxation, 257–258
Shoulder sweep exercise, for thoracic spine, 1417–1419, 1417f
thoracic spine extension, 1418, 1418f
thoracic spine flexion, 1417, 1418f
thoracic spine rotation, 1418–1419, 1418f–1419f
thoracic spine side bending, 1419, 1419f
Sickle-cell disease, foot pain, 272
Sickness Impact Profile (SIP), 1471–1472
Side bending, 1438
Side-glide test, 1451, 1452t
Side gliding, 1482
Side-lying test, for BPPV, 1228
Sign of buttock, 951
SIJ. See Sacroiliac joint (SIJ)
Simple Shoulder Test (SST), 620–621, 621t
Sinding–Larsen–Johanssen syndrome, 1059
Single-leg bridges on Swissball, 1027, 1027f
Single-legged hyperextension test, 1582, 1582f
Single-leg squat test, 1022–1023
Single photon emission computed tomography (SPECT), 364–365
Sinusitis, acute, 237
Sinus tarsi, 1088–1089, 1116
Sinus tarsi syndrome, 1155–1156
Sinuvertebral nerve, 1427
Sit-stand-sit activities, 562
Sitting arm lift test, for thoracic spine, 1409, 1409f

Sitting root test, 449
Six-minute walk test (6MWT), 321
Six-position test, 1459–1463
  double knees to chest, 1460, 1460f
  hook-lying position, 1460, 1460f
  key muscle tests, 1461
    ankle eversion, 1463, 1464f
    dorsiflexors testing, 1462, 1462f
    great toe extension, 1463, 1464f
    heel walking, 1462, 1462f
    hip extension, 1463, 1463f
    hip flexion, 1462, 1463f
    knee extension, 1462–1463, 1463f
    knee flexion, 1463, 1464f
    standing up on toes, 1461–1462, 1461f
    unilateral squats, 1462, 1462f
  muscle strength, 1461
  prone double knee bend, 1461, 1461f
  prone lying with legs straight, 1460, 1461f
  single knee to chest, 1460, 1460f
  supine lying, 1460, 1460f
Skeletal demineralization, risk factor reduction for, 929
Skeletal fracture, in pediatric patients, 1572
  avulsion, 1572
  clinical presentation, 1573
  greenstick fracture, 1572
  growth plate fractures, 1572
  intervention, 1573
  Salter and Harris classification for physeal fractures, 1572
Skeletal malalignment, 328t–329t
Skeletal muscle relaxants, 405
Skeletal traction, for fractures, 54
Skier's thumb, 828, 845
SLAP lesions, 671
Slide joint movement, 21–22, 21f
Slipped capital femoral epiphysis (SCFE), 990, 1580, 1581t
Slouched posture, 330
Slouch/overcorrect maneuver, 1482
Slow-twitch fibers, 10
Slump test, 448–450, 450f
  Bechterew's test, 449
  femoral, 449, 449f
  sitting root test, 449
  for thoracic spine, 1408
Small weights, in resistance training, 502
Smith fracture
  Barton fracture, 856
  buckle fracture, 856
  type I/II/III, 856
Snapping hip (coxa sultans)
  extra-articular, 939
  intra-articular, 939
Snapping scapula, 688
Sodium channel blockers, 408
Soft tissue extensibility increasing technique, 860. See also Joint mobility increasing techniques
  biceps, 770
  elbow and wrist flexors, 770
  iliopsoas, 955
  iliopsoas and rectus femoris, 955–956
  iliotibial band, 955
  stretch for Golfer's elbow, 770–771
  tensor fascia latae, 956
  weight-bearing wrist flexor stretch, 771
  wrist and finger extensors, 770
Soft tissue injuries, 32
  acute, 32
  chronic, 33
  classification of, 32–33
  healing of, 33–36
    coagulation and inflammatory stage, 34–35
    factors impacting, 34t
    migratory and proliferative stage, 35–36
    remodeling stage, 36
    stages of, 33f, 34–36
  microtraumatic injuries, 33
  subacute, 32
Soft-tissue mobilizations (STMs), 424–425, 945
Soft-tissue techniques, 422–428
  acupressure, 425
  craniosacral therapy (CST), 428
  functional techniques, 428
  general massage, 425
  ischemic compression, 425
  muscle energy technique, 425–426
  myofascial release, 423–424, 424t
  myofascial stroking, 424
  soft-tissue mobilizations (STMs), 424–425
  strain-counterstrain (positional release) technique, 426–428, 427f
  sustained pressure, 425
  transverse friction massage (TFM), 422–423
Sole physical therapy management, 126t
Soleus muscle, leg and foot, 491, 491f
Somatic dysfunction of wrist, 812
Somatosensory Amplification Rating Scale (SARS), 118, 119t
Sorensen test for extensors, 1464, 1465f
SPADI. See Shoulder Pain and Disability Index (SPADI)
Spastic gait, 314
Spastic hemiplegic (hemiparetic) gait, 314
Spasticity, 123
Spastic paraparetic gait, 314
Special tests, 201–202
  clearing tests, 202
  provocative tests, 201–202
Specific adaptation to imposed demand (SAID) principle, 496
Specific muscle testing. See Manual muscle testing (MMT)
SPECT. See Single photon emission computed tomography (SPECT)
Speed's test, 640, 641f
Speed–strength training, 496–497
Sphenoid sinuses, 237
Spherical grasp, 803
Spinal accessory nerves, 78
Spinal cord, 65–67, 66f
Spinal instability, 1500
  clinical findings, 1500
  diaphragm activation, 1502
  extremity loading, 1502, 1502f
  functional movements, 1502
  rhythmic stabilization, 1502
  unstable base, 1502
emphasis on abdominals
  abdominal crunch, 1503–1506, 1504f
  back extensor endurance test, 1504
  bent-leg fall out, 1502
  emphasis on lateral stabilizers, 1505, 1505f–1506f
  emphasis on trunk extensors, 1504, 1504f–1505f
  flexion endurance test, 1504, 1504f
  lateral musculature test, 1506, 1506f
  progressive limb loading, 1502–1503, 1503f
emphasis on athletic performance
  hip thrusts, 1508, 1509f
  prone lying on Swiss ball, hands touching floor, 1509, 1510f
  prone plank, 1509, 1510f
  push-ups with legs on chair, 1511f
  reverse curl up, 1509, 1509f
  rhythmic stabilization, 1511, 1511f
  rotational partial sit-up, 1508–1509, 1509f
  stirring the pot, 1509, 1510f
  superman position, 1509, 1510f
emphasis on function
  backward lunge, 1507
  bridging, 1506–1507, 1507f
  chop and lift, 1507–1508, 1508f
  forward lunge, 1507, 1507f
  wall slides, 1507
intervention, 1500
  abdominal bracing, 1501
  multifidus activation, 1501–1502, 1501f
  transversus abdominis (TrA) exercise, 1500–1501, 1501f
muscle imbalances, correction of, 1511
pelvic floor muscle activation, 1502
trunk balance exercises, 1511–1513, 1512f–1514f
Spinal motion, 1193–1195

and finger extensors, 770
flexion, 732, 801, 813, 830, 840
test, 823
flexors, 770
frontal lateral movements of, 801
functional testing of, 818t
ganglia, differential diagnosis of, 264t
infections, 263
joints, 859
joints, goniometry of, 536–537, 537f–538f
flexion and extension, 536–537, 537f

Wrist. See also Forearm, wrist, and hand; Muscles (continued)
radial deviation and ulnar deviation, 537, 538f
ligaments of, 784t
motion of, 817t
movements and digits, 801–802
MRI, 363
muscles of, 790–794, 790t
muscles testing of, 479–482, 480f–483f
abductor pollicis longus, 482, 482f
extensor carpi radialis brevis, 481, 481f
extensor carpi ulnaris, 481, 481f
extensor digiti minimi, 481, 481f
extensor digitorum communis, 481, 481f
extensor indicis, 482, 483f
extensor pollicis brevis, 482, 482f
extensor pollicis longus, 482, 482f
flexor digitorum profundus, 480, 480f
flexor digitorum superficialis, 480, 480f
flexor pollicis longus, 480, 480f
palmaris longus, 479–480, 480f
in neutral
with fingers and thumb extended, 458f
with fingers and thumb in flexion, 458f
radial deviation at, 801
radiography, 355–356
sprain, 844
strength testing, 814
vasculature of, 796–799
Wrist, hand, and finger pain, causes of, 261–265, 262f, 263t
felon, 263–264
ganglia, 264, 264t
gout and pseudogout, 263
herpetic whitlow, 264
infection, 263–264
Kienböck disease, 264
mononeuritis multiplex, 265
peripheral nerve entrapment, 265
Raynaud phenomenon, 265
referred pain, 265
rheumatoid arthritis, 263
scleroderma, 265
tumors, 264–265
vascular occlusion, 265
web space abscess, 264
Wrist extensors, gross muscle testing, 469f
Wrist flexion ball flips, 841
Wrist flexors, gross muscle testing, 469f
Wrist ratio index, 832, 832t

Yeoman's test, 1550, 1550f
Yergason's test, 641, 641f
Yocum test, 635, 636f
Yoga, 336, 853

Zohler sign, 1013, 1014f
Zygapophyseal joints, 1191, 1385, 1428–1429. See also Lumbar spine; Vertebral column
anatomy, 1259
combined motions of, 1407, 1407f
dysfunction, 1318, 1499
extension of, 1407, 1407f
flexion of, 1406, 1407f
functions of, 1428
hypomobility of, 1499
intraarticular meniscoids, 1428
nerve supply, 1435
shape, 1428
whiplash-associated disorder and, 1320–1321
Zygomatic arch, 1362
